Brain morphology in antipsychotic-naïve schizophrenia: a study of multiple brain structures*

Background Although brain volume changes are found in schizophrenia, only a limited number of structural magnetic resonance imaging studies have exclusively examined antipsychotic-naïve patients.

Aims To comprehensively investigate multiple brain structures in a single sample of patients who were antipsychotic-naïve.

Method Twenty antipsychotic-naïve patients with first-episode schizophrenia and 20 healthy comparison subjects were included. Intracranial, total brain, frontal lobe, grey and white matter, cerebellar, hippocampal, parahippocampal, thalamic, caudate nucleus and lateral and third ventricular volumes were measured. Repeated-measures analyses of (co)variance were conducted with intracranial volume as covariate.

Results Third ventricle volume enlargement was found in patients compared with the healthy subjects. No differences were found in other brain regions.

Conclusions These findings suggest that some brain abnormalities are present in the early stages of schizophrenia. Moreover, it suggests that brain abnormalities reported in patients with chronic schizophrenia develop in a later stage of the disease and/or are medication induced.

Declaration of interest None.

Numerous imaging studies have reported morphological brain abnormalities in schizophrenia, including studies in first-episode schizophrenia (for reviews see McCarley et al, 1999; Wright et al, 2000). However, it is difficult to establish whether these structural brain abnormalities are caused by the disease or are from the effects of treatment. Imaging studies in patients with schizophrenia who have never been exposed to antipsychotic medication may help to clarify whether brain changes are already present in an early stage of the disease and are independent of medication use. This current study examined multiple brain structures in a single sample of antipsychotic-naïve patients with schizophrenia compared with a sample of carefully matched healthy comparison subjects. Intracranial volume, total brain, grey and white matter of the cerebrum, frontal lobe, cerebellar, hippocampal, parahippocampal, thalamic, caudate nucleus and lateral and third ventricular volumes were assessed.

As evidence is accumulating that medication may alter brain structures (increases in basal ganglia volumes have been related to antipsychotic intake (Chakos et al, 1994; Keshavan et al, 1994; Scheepers et al, 2001) and decreases in frontal lobe volume have been related to the amount of antipsychotic medication used (Gur et al, 1998a; Madsen et al, 1998)), the study of brain morphology in antipsychotic-naïve patients with schizophrenia is crucial for an understanding of the disease. Studies comparing antipsychotic-naïve patients with first-episode schizophrenia with healthy comparison subjects have examined only one or a few brain structures (Table 1). These studies have inconsistently reported brain volume changes in antipsychotic-naïve patients with schizophrenia compared with healthy volunteers, which could be caused by factors such as a large variation in scanning acquisition and volumetric measures, inclusion of small numbers of subjects, inclusion of patients with a diagnosis other than schizophrenia and failure to match for age, gender, socioeconomic class or handedness. In addition, some studies were not designed to exclusively compare antipsychotic-naïve patients with healthy comparison subjects.

METHOD

Subjects

Twenty patients in their first psychotic episode of schizophrenia were recruited from the First-Episode Schizophrenia Research programme at the University Medical Centre Utrecht. Patients had not received antipsychotic treatment prior to scanning. All patients met DSM-IV (American Psychiatric Association, 1994) criteria for schizophrenia (11 paranoid, 8 undifferentiated, 1 disorganised type), on the basis of the Comprehensive Assessment of Symptoms and History (CASH; Andreasen & Arndt, 1992) rated by two independent raters. Nineteen patients (one patient was lost to follow-up) had the diagnosis confirmed after 1 year. The start of prodromal symptoms and psychotic illness was measured by a shortened version of the Interview for the Retrospective Assessment of the Onset of Schizophrenia (IRAOS; Hafner et al, 1992). Severity of illness was measured with the Positive and Negative Syndrome Scale (PANSS; Kay et al, 1987). Twenty healthy comparison subjects were recruited and carefully matched for gender, age, parental education and handedness. They were all screened with the Schedule for Affective Disorders and Schizophrenia – Lifetime Version (SADS-L; Endicott & Spitzer, 1978) and fulfilled criteria for ‘never mentally ill’. All subjects were physically healthy (except one patient who had congenital hypothyroidism, but was stable on supplementation medication), had neither a history of head injury nor a diagnosis of drug or alcohol misuse or dependence. All patients and healthy comparison subjects provided written informed consent to participate in the study. For demographic and clinical data see Table 2.

Brain imaging

MRI acquisition

Magnetic resonance images (MRIs) were acquired on a Philips NT scanner operating at 1.5 T. A T1-weighted three-dimensional fast field echo (3D-FFE: echo time (TE)=4.6 ms, repetition time (TR)=30 ms, flip angle=30°, field of view...

(FOV)=256/80% mm) with 160–180 contiguous coronal 1.2-mm slices, and a T2-weighted dual echo turbo spin-echo DTSE: TE1=14 ms, TE2=80 ms, TR=6350 ms, flip angle=90°, FOV=256/80% mm) with 120 contiguous coronal 1.6-mm slices of the whole head were used for the quantitative measurements. In addition, a T2-weighted DTSE (TE1=9 ms, TE2=100 ms, TR=2200 ms, flip angle=90°, FOV=250/100% mm) with 17 axial 5-mm slices and 1.2-mm gap of the whole head was acquired for clinical neurdiagnostic evaluation. Processing was carried out on the neuroimaging computer network of the Department of Psychiatry. Before quantitative assessments, 10 images were randomly chosen and cloned for interrater reliability purposes determined by the intraclass correlation coefficient (ICC). All images were coded to ensure blindness for subject identification and diagnosis, scans were entered into Talairach frame (no scaling) (Talairach & Tournoux, 1988) and corrected for inhomogeneities in the magnetic field (Sled et al, 1998).

**Volume measurements**

Intracranial, total brain, cerebral grey and white matter, lateral ventricles and third ventricle and cerebellar volumes were measured automatically by using histogram analysis algorithms and series of mathematical morphological operators to connect all voxels of interest (Schnack et al, 2001a,b). Intracranial volume was segmented on the DTSE scans, with the foramen magnum being used as inferior boundary. Total brain volumes were segmented on the 3D-FEE (T1-weighted) scans and contained grey and white matter tissue only. In lateral ventricle segmentation automatic decision rules bridged connections not detectable and prevented ‘leaking’ into cisterns. The third ventricle was limited by coronal slices, clearly showing the anterior and posterior commissures; the upper boundary was a plane through the plexus choroides ventriculi tertiī in the mid-sagittal slice perpendicular to this slice. The cerebellum was limited by the tentorium cerebelli and the brain-stem. All images were checked after the measurements and corrected manually if necessary. The interrater reliability of the measurements determined by the ICC based on 10 brains was 0.95 and higher. Segmentation of the frontal lobe was performed automatically using the ANIMAL anatomical segmentation algorithm (Collins et al, 1994), which was validated previously for frontal lobe volume measurements (Mandl et al, 1999).

Quantitative measurements of the caudate nucleus, thalamus, hippocampus and parahippocampus were obtained manually, from the 3D-FEE image using Analyze™ (Robb, 1995). The caudate nucleus was anteriorly defined in the first slice in which it was clearly visible. Its medial border was the lateral ventricle. Laterally, it was limited by the internal capsule, excluding the interconnecting grey matter striate between caudate and putamen visible in the internal capsule; posteriorly, by the last slice before the one in which the posterior commissure was clearly visible. Its inferior border was defined: anteriorly by the white matter connecting the rostrus corporis callosi and the capsule externa. Then, from the first slice where the putamen is clearly visible until the slice anterior to the slice in which the anterior commissure crosses the midline, the nucleus accumbens was separated by a line from the most inferior point of the lateral ventricle to the most inferior point of the internal capsule (adapted from Chakos et al, 1994). The thalamus was anteriorly defined in the first slice in which it was clearly visible, and precisely demarcated in the subsequent slices until the first slice after the coronal slice that included the posterior commissure. Its lateral border was defined by the internal capsule; its medial border by the third ventricle and its inferior boundary was defined by the anterior commissure–posterior commissure plane. Segmentation of the hippocampus was started in the coronal slice in which the mammillary bodies were visible and stopped when the fornix was visible as a continuous tract (adapted from Watson et al, 1992). Parahippocampal gyrus segmentation began in the coronal slice in which the optic tract is situated above the amygdala. The posterior commissure was its posterior border. Single operators performed the volume measurements of the above-named structures. The ICC for the left and right caudate nucleus was 0.98 and 0.99, for the thalamus, 0.77 and 0.86, for the hippocampus, 0.81 and 0.80 and for the parahippocampal gyrus, 0.77 and 0.75.

**Statistical analyses**

Repeated-measures analysis of covariance was conducted for total brain, grey and white matter of the cerebrum (total brain, excluding cerebellum and brainstem), frontal lobe, cerebellum, hippocampus, parahippocampus, thalamus, caudate volumes and ventricles, with group (patients, healthy comparison subjects) as the between-subjects variable and, if applicable, side (left, right) and matter (grey, white) as the within-subjects variable. Intracranial brain volume served as covariate for total brain, grey and white matter of the cerebrum, cerebellum, lateral and third ventricle volume measures. Total brain volume served as covariate for frontal lobe, hippocampal, parahippocampal, thalamic and caudate volumes.

To examine associations between significant brain volume differences and clinical variables (prodromal phase, duration of untreated psychosis, PANSS scores) Pearson’s correlations were calculated with intracranial volume as a covariate. To assess the power of the study a power analysis, uncorrected for intracranial volume, was carried out with a probability of 0.7 at an \( \alpha \) level of 0.05.

**RESULTS**

As seen in Table 2, patients and healthy comparison subjects did not significantly differ for gender, handedness, age, weight and parental education. Although not matched for education, patients did not differ from healthy comparison subjects on years of education. Patients and healthy comparison subjects did significantly differ in height, but as intracranial volume was used as covariate, the results presented below are uncontrolled for height. However, results did not change when height was used as a covariate.

Mean (s.d.) volumes of total brain, frontal brain, grey matter, white matter, cerebellum, hippocampus, parahippocampus, thalamus, caudate nucleus, lateral ventricles and third ventricle are presented in Table 3 for patients and healthy comparison subjects.

**Intracranial volume and total brain measures**

Intracranial volume (\( F=2.59, \text{d.f.}=1.38, P=0.12 \)), total brain volume (\( F=0.55, \text{d.f.}=1.37, P=0.47 \)) and cerebral volume (\( F=0.36, \text{d.f.}=1.37, P=0.56 \)) did not differ significantly between the two groups, nor was there a significant interaction effect of group with matter (grey, white) of the cerebrum (\( F=0.21, \text{d.f.}=1.38, P=0.65 \)).

**Frontal lobe and cerebellum**

Frontal lobe volume (\( F=0.34, \text{d.f.}=1.37, P=0.56 \)) and cerebellar volume (\( F=0.34, \text{d.f.}=1.37, P=0.57 \)) did not differ significantly between the two groups.

**Hippocampus, parahippocampus, thalamus and caudate nucleus**

Hippocampus (\( F=0.11, \text{d.f.}=1.37, P=0.74 \)), parahippocampus (\( F=2.05, \text{d.f.}=1.37, P=0.16 \)), thalamus (\( F=0.28, \text{d.f.}=1.37, P=0.60 \)), and caudate nucleus (\( F=1.23, \text{d.f.}=1.37, P=0.27 \)) did not differ significantly between the two groups.

**Ventricles**

Lateral ventricle volume (\( F=0.15, \text{d.f.}=1.37, P=0.70 \)) did not significantly differ between the two groups. However, third ventricle volume was significantly larger in patients compared with the comparison subjects (\( F=8.92, \text{d.f.}=1.37, P=0.005 \)) (Fig.1).

No significant interaction effects of group with matter or with side for any of these measures were found. No correlations were found between third ventricle volume and the clinical data. Excluding the patient with congenital hypothyroidism and her matched comparison subject did not alter the results.

**DISCUSSION**

This study compared multiple brain structures in a sample of antipsychotic-naive patients with schizophrenia with those of matched healthy comparison subjects. Volumes of the cranium, total brain, grey and white matter of the cerebrum, frontal lobe, cerebellum, hippocampus, parahippocampus, thalamus, caudate nucleus and lateral and third ventricles were measured. We found third ventricle enlargement in the patients. The other structures were similar in both patients with schizophrenia and healthy comparison subjects.

**Third ventricle enlargement in antipsychotic-naive patients with schizophrenia**

To our knowledge, third ventricle volume has not been examined with MRI in patients with schizophrenia who were antipsychotic-naive. Third ventricle enlargement has been reported in studies of first-episode schizophrenia examining mixed (antipsychotic-naive and -treated subjects) samples of patients (for review

see Fannon et al, 2000). A possible volume reduction in surrounding diencephalic brain regions could explain the third ventricle enlargement, although in our study this was not expressed in a reduction of thalamic volume. The absence of a reduction in thalamic volume in our study is consistent with the studies performed in antipsychotic-naïve patients with schizophrenia (Buchsbaum et al, 1996; Gur et al, 1998b). Interestingly, third ventricle enlargement but also thalamic volume decrease were found in the healthy siblings of patients with schizophrenia (Staal et al, 1998, 1999, Jansen, 1991; Jansen, 1998), suggesting that these findings could be related to a genetic vulnerability for schizophrenia. The discrepancy of an increase of third ventricle without a corresponding decrease in thalamic volume in this study might be related to the relatively limited number of patients included, or could imply that other regions in the proximity of the third ventricle, such as the hypothalamus, are involved. Abnormalities in the hypothalamic–pituitary–adrenal axis have been suggested to be present in schizophrenia (Tandon et al, 1991; Jansen et al, 2000; Walder et al, 2000); however, to date no study has been published measuring the hypothalamus in schizophrenia.

No volume changes in brain tissue
This study found normal total brain and frontal lobe volume in antipsychotic-naïve patients. This finding is inconsistent with the findings by Gur et al (1998a, 2000b), demonstrating total brain and frontal lobe reduction, specifically in prefrontal grey matter, in antipsychotic-naïve patients with schizophrenia. In these studies, however, a mixed sample of antipsychotic-naïve patients and previously treated patients with schizophrenia was examined. Our finding of a normal hippocampus in antipsychotic-naïve patients is congruent with the only other MRI study (Laakso et al, 2001) designed to examine hippocampal volumes in antipsychotic-naïve patients compared with healthy comparison subjects. Similar caudate nucleus volumes in both antipsychotic-naïve patients and healthy comparison subjects have also been reported in one study (Gur et al, 1998b), but not in others (Keshavan et al, 1998a; Shihabuddin et al, 1998; Corson et al, 1999). The latter studies found reduced volumes in patients. Differences in the various samples, such as diagnosis and handedness, as well as variations in quantitative assessment techniques might explain these inconsistencies.

Relative paucity of brain abnormalities
The relative paucity of brain abnormalities found in this study may actually be the most striking finding. It stands in marked contrast with findings in patients with more chronic schizophrenia, where volume reductions in total brain and medial temporal lobe structures as well as volume enlargement of lateral ventricles have been reported consistently (for review see Wright et al, 2000). However, the most likely reason for this relative paucity of brain abnormalities is a lack of power, as only 20 patients and 20 healthy comparison subjects were included in this study. Several other explanations, besides the lack of power, can be suggested to explain this discrepancy. First, progression of the illness could lead to an increase of brain abnormalities. A limited number of longitudinal studies in patients with first-episode schizophrenia have been conducted suggesting that brain abnormalities may indeed become more prominent over time (DeLisi et al, 1997; Gur et al, 1998a) at least in a subgroup of patients with poor outcome (Lieberman et al, 2001). Second, medication might increase brain abnormalities and could contribute to these brain volume changes as suggested by Gur et al (1998a) and Madsen et al (1998). Third, finding few brain abnormalities in antipsychotic-naïve patients could be the result of a selection bias favouring the inclusion of patients who have a less severe form of schizophrenia. Two characteristics of our sample, high education and a later age of onset, suggest it might indeed not be representative of all patients with first-episode schizophrenia. In our study no difference between patients and healthy comparison subjects on years of education existed. A total of 9 patients of 20 had even completed part or all of university training. In addition, their mean age at onset was at about 27 years. Interestingly, high education and a later age of onset are both related to good outcome (Johnstone et al, 1989; Weisegren & Lindstrom, 1996), which in turn appears to be associated with a relative lack of brain abnormalities at presentation of illness (Staal et al, 1999b). It has also been
suggested that grey matter volume is related to IQ (Andreasen et al, 1993). Therefore, in this study a level of education (and presumably premorbid IQ) similar in patients to that of the healthy comparison subjects could have resulted in finding no decrements in (regional) grey matter volume. Thus, although the relative paucity of brain volume abnormalities in our sample could be indicative of progressive brain changes in schizophrenia because of illness and/or medication, alternatively it could have been the result of a selection bias that may be hard to avoid when studying antipsychotic-naive patients with schizophrenia.

**Future studies**

Although it may be practically impossible to determine whether brain abnormalities in schizophrenia result from the progression of the illness and/or medication, the suggestion of medication having an effect on brain volume changes should be an incentive for future longitudinal studies to carefully monitor medication intake.

**CLINICAL IMPLICATIONS**

- Third ventricle enlargement in antipsychotic-naive first-episode patients with schizophrenia suggests abnormalities in schizophrenia in the diencephalic region of the brain at the onset of the disease.
- Antipsychotic medication might be partly implicated for brain abnormalities found in schizophrenia.
- The relative paucity of brain abnormalities in patients with first-episode schizophrenia suggests that an underlying neurodegenerative process cannot be excluded.

**LIMITATIONS**

- The study group was relatively small as a result of the inclusion requirements such as no prior antipsychotic use and no illicit drug or alcohol misuse/dependence, which is highly prevalent in first-episode schizophrenia.
- Although previous education in patients suggested a high (premorbid) IQ, no formal IQ testing was performed.
- Patients were carefully matched to the healthy comparison subjects but they did significantly differ in height. However, when height was used as a covariate results did not change.

Brain morphology in antipsychotic-naïve schizophrenia: a study of multiple brain structures
