Effect of a structured educational intervention on explanatory models of relatives of patients with schizophrenia

Randomised controlled trial

S. DAS, B. SARAVANAN, K. P. KARUNAKARAN, S. MANORANJITHAM, P. EZHILARASU and K. S. JACOB

Summary We examined the effect of a structured educational programme on explanatory models of illness among the relatives of people with schizophrenia, in a randomised controlled trial. Participants were assessed at baseline (n=100) and after 2 weeks (n=75) using a vignette from the Short Explanatory Model Interview. There was a reduction in non-biomedical causal explanatory models at follow-up among those who had completed the structured educational programme compared with the control group. There was no significant difference in non-biomedical treatment explanatory models between the two groups.

Declaration of interest None.

METHOD

Out-patients who attended the Department of Psychiatry, Christian Medical College, Vellore, India for the first time and who satisfied ICD–10 (World Health Organization, 1993) diagnostic criteria for a research diagnosis of schizophrenia were invited to participate in the study with their relatives (Fig. 1). Patients continued to be managed by their psychiatrists. Informed consent was obtained from the relatives, who were then randomised in blocks of four, using a computer program, to a group that would receive the structured educational intervention or to a control group. Progress through the trial is shown in Fig. 1.

The Short Explanatory Model Interview (SEMI; Lloyd et al, 1998) formed the basis of the evaluation. A vignette describing a typical patient with chronic psychosis was presented (Joel et al, 2003). This was followed by open-ended questions to elicit the relatives’ beliefs about the perceived causes and consequences of the condition, and help-seeking behaviour. A verbatim record of the responses was made, and these were later grouped into categories using the procedure recommended by the SEMI. The Tamil version of the instrument was employed (Joel et al, 2003). Basic demographic and clinical information was also recorded. The assessments were conducted on day 1 (baseline) and after 2 weeks of a structured educational programme in the intervention group. The research nurse who performed the evaluations was masked to the intervention status of the participants.

We developed a structured educational programme which discussed the different explanatory causal and treatment models prevalent in the region, and we also presented the biomedical perspective without dismissing or directly challenging local beliefs. This intervention had three components: exploring explanatory models; psychoeducation, aimed at teaching the relatives about the illness, symptoms, treatment and prognosis; and strategies to reduce the risk of relapse. The education package covered the following topics in two sessions: symptoms, beliefs about causation, psychosocial influences, prevalence, biomedical model, diagnosis, treatments (including medication and adherence), and coping strategies for families.

Sample size was calculated assuming that half of those who receive education and one-fifth of those who do not would consider the illness to have a medical cause by the end of the trial. For a power of 80% and 95% confidence the minimum sample required was 72 (36 in each arm). To compensate for possible loss to follow-up we recruited 100 participants.

RESULTS

A total of 100 patients and 100 relatives (one first-degree relative per patient) were contacted, all of whom agreed to take part in the study. The majority of the participants were male (56%), married (91%) and literate (80%), with a mean age of 45.3 years (s.d. = 15.7). Most of the participants (60%) regarded the condition of the patient described in the vignette as a disease. Nearly all of the relatives who were interviewed (94%) felt that help should be sought from a doctor or hospital. However,
a significant proportion of the relatives also attributed the patient’s condition to previous deeds (43%) or to punishment by God (43%), and felt that visiting temples and places of worship could solve the problem (33%). A minority of participants attributed the patient’s condition to black magic (33%) or evil spirits (10%), and felt that help should be sought from a traditional healer (3%) or a shaman (9%). The majority of participants held more than one explanatory model of illness, and many believed that there was at least one non-biomedical explanation for the patient’s psychosis. The differences between the baseline socio-demographic variables and the explanatory models of the two groups were not statistically significant.

The 25 participants lost to follow-up (see Fig. 1) did not differ significantly from those assessed at 2 weeks with regard to socio-demographic variables, explanatory models at baseline, or treatment arm.

Intent-to-treat analysis of all participants (with the last observation carried forward for those who were lost to follow-up) showed that the intervention group had a statistically significant reduction in the total number of non-biomedical causal models of psychosis compared with the group of relatives who did not receive additional education (mean = 0.88 (s.d. = 0.96) v. 1.32 (1.15); P = 0.08). The two groups also showed a significant difference with regard to change in non-medical causal models from baseline after adjusting for age, gender and literacy (mean = –0.58 (s.d. = 1.21) v. 0.14 (1.16); P = 0.003). There were significant differences between the two groups at follow-up in the number attributing the condition to black magic (8 v. 16; P = 0.08) and the number believing that visiting a place of worship would effect a cure (7 v. 14; P = 0.04). However, there were no differences between the two groups with regard to non-medical treatment models of illness (see data supplement to online version of this paper). Similar results were obtained when the data for participants who completed the trial were analysed.

**DISCUSSION**

This study evaluated an educational intervention for psychosis and assessed its effect in the immediate follow-up period. Limitations included the drop-out rate of 25% and the lack of long-term assessment. However, the participants who were lost to follow-up did not differ significantly in terms of baseline variables from those who remained in the trial. Also, the results of an intent-to-treat analysis and analysis of those who completed the trial were similar.

The baseline data suggest that the relatives of patients with psychosis have multiple, diverse and contradictory explanatory models of illness. Participants held simultaneous beliefs in naturalistic explanations (e.g. disease) and personalistic explanations (e.g. supernatural causation, sin and punishment, karma). They also suggested that help could be sought from a range of different sources (e.g. doctor, temple or place of worship, traditional healer). Other studies of explanatory models of psychosis have reported similar findings (Joel et al, 2003), and the issues surrounding the simultaneous holding of multiple beliefs have been discussed in the literature (Saravanan et al, 2004, 2005).

The educational intervention programme used in this study discussed the local explanations for psychosis, and presented the biomedical explanatory model as an alternative. The indigenous beliefs of the participants were not challenged. The programme did not claim exclusivity or superiority of biomedical beliefs, but discussed issues relating to symptoms, disease models, medication and regular treatment. Although such issues are often raised in routine clinical practice (and the control group may also have received such information), psychoeducation does not follow a structured format, and psychiatrists tend to dismiss local explanations and to favour biomedical concepts.

The relatives who received the educational intervention showed some change in their explanatory models in the immediate follow-up period. However, many of the indigenous explanatory models persisted, especially those related to treatment. The results of this study suggest that although some explanatory models can be changed, others may be more resistant to modification. In the developing world, people with mental disorders often visit places of worship, traditional healers and psychiatric hospitals in search of both relief from symptoms and cure (Jacob, 1999). However, it is acknowledged that holding non-biomedical beliefs about psychosis can delay the recognition of disease, prevent early institution of treatment with medication, and interfere with adherence to treatment, resulting in a poor outcome.

Health education packages should discuss the advantages of medication, but should not dismiss alternative explanations of illness, as these may also help to restore mental health. Further research is needed to identify the components of the ideal health education package and maximise its effectiveness in changing explanatory models and thereby preventing relapse.
