Cognitive dysfunction in first-episode psychosis: the processing speed hypothesis*

JOSE MANUEL RODRIGUEZ-SANCHEZ, BENEDICTO CRESPO-FACORRO, CESAR GONZALEZ-BLANCH, ROCIO PEREZ-IGLESIAS and JOSE LUIS VAZQUEZ-BARQUERO on behalf of the PAFIP Group Study

Background Speed of processing is a cognitive process underlying cognitive dysfunction in people with chronic schizophrenia.

Aims To investigate the contribution of speed of processing to the cognitive deficits observed in a representative large sample with first-episode schizophrenia.

Method People with a diagnosis of first-episode schizophrenia-spectrum disorders (n = 26) and healthy controls (n = 28) were compared on several cognitive measures before and after controlling for speed of processing.

Results Before controlling for speed of processing, patients and controls differed significantly on all cognitive measures. All significant differences in cognitive functioning disappeared when the result of the Digital Symbol Substitution Test was included as an additional covariate.

Conclusions Speed of information processing may be considered a core cognitive deficit in schizophrenia and might be mediating a broader diversity of cognitive disturbances.

Declaration of interest None.

Funding detailed in Acknowledgements.

People with schizophrenia show cognitive impairments on most cognitive domains from the very early phases of the disease (Gonzalez-Blanch et al, 2007). Since cognitive functions are not completely independent from each other, it is still unclear whether this generalised disturbed cognitive profile is a reflection of a widespread dysfunction or a consequence of a primary deficit in a core cognitive function. Speed of processing is a core cognitive process underlying cognitive dysfunction in normal ageing (Saltouse, 1993), traumatic brain injury (Rios et al, 2004), depression (Egeland et al, 2003) and Parkinson’s disease (Rogers et al, 1987). Deficits in speed of processing may determine impairments of declarative memory (Brebin et al, 1998, 2000; Holthausen et al, 2003) or working memory (Hartman et al, 2002) in people with chronic schizophrenia. However, it remains to be elucidated whether these associations are already present in the early stages of schizophrenia. The aim of this study was to investigate the contribution of speed of processing to the cognitive deficits observed in a representative large sample with first-episode schizophrenia.

METHOD

Study setting

The data for these analyses were taken from a large epidemiological and longitudinal (3-year) intervention programme of first-episode psychosis (PAFIP) carried out in Cantabria, Spain (Crespo-Facorro et al, 2006). The study was conducted at the outpatient clinic and the in-patient unit of the University Hospital Marques de Valdecilla in Santander (Cantabria). The study was designed and directed by B.C.-F. and J.L.V.-B., conforming to international standards for research ethics and was approved by the local institutional review board.

Participants

From February 2001 to October 2005 all referrals to PAFIP were screened for the following eligibility criteria: (a) aged 15–60 years; (b) meeting DSM-IV criteria (American Psychiatric Association, 1994) for a principal diagnosis of schizophrenia, schizophreniform disorder, schizoaffective disorder, brief reactive psychosis, schizophrenic personality disorder or psychosis not otherwise specified; (c) no prior treatment with antipsychotic medication or, if previously treated, a total lifetime of adequate antipsychotic treatment of less than 6 weeks. Patients meeting these criteria and their families provided written informed consent for inclusion in the PAFIP programme. The diagnoses were confirmed using the Structured Clinical Interview for DSM-IV (SCID-I; First et al, 2001) by an expert psychiatrist 6 months after the initial contact. Only those people with mental retardation (DSM-IV criteria) or drug dependence (DSM-IV criteria) were excluded.

Out of 174 consecutive admissions that met the criteria for enrollment, 43 people declined to participate in the study. A final sample of 131 patients (85 males, 46 females) completed the baseline neurocognitive assessment. No significant differences between patients who did and did not complete cognitive assessment were found in relevant variables such as age, gender, duration of illness, or clinical severity. From these 131 patients, only 126 with a final diagnosis of schizophrenia, schizophreniform disorder, brief psychotic disorder and psychosis not otherwise specified at 6 months by SCID-I were considered for this study.

At the time of the cognitive evaluation, 42 patients were taking conventional (haloperidol) and 84 atypical antipsychotics (41 olanzapine and 43 risperidone). Clinical symptoms were rated using the Scale for the Assessment of Negative Symptoms (SANS; Andreasen, 1983) and the Scale for the Assessment of Positive Symptoms (SAPS; Andreasen, 1984). Duration of untreated illness was defined as the time from the first non-specific symptoms related to psychosis (for such a symptom to be considered, there should be no return to the previous stable level of functioning) to the initiation of adequate antipsychotic drug treatment. Duration of untreated psychosis was defined as the time from the first continuous (present most of the time) psychotic...
symptom to initiation of adequate antipsychotic drug treatment.

A sample of healthy controls (n=28) recruited from the local area through advertisement was submitted to the same cognitive assessment. Antecedents of psychiatric disturbance in the control group were excluded by means of the Comprehensive Assessment of Symptoms and History (CASH; Andreasen et al., 1992).

Neuropsychological assessment

Patients and controls were submitted to a broad neuropsychological battery. This was carried out once clinical stability had been achieved in order to maximise collaboration. This occurred typically at a mean of 10.72 (s.d.=3.97) weeks after intake into the programme.

In order to reduce type I error on statistical analyses, variables obtained from neuropsychological tests were grouped into cognitive domains following results from previous factor analysis. A detailed description of the cognitive battery employed, the procedure for factor analysis and the final composition of cognitive factors is provided elsewhere (Gonzalez-Blanch et al., 2007).

From eight basic cognitive domains, we decided to examine those key cognitive dimensions with a more pronounced impairment (around 1 s.d. below healthy controls): executive functions, verbal memory, attention and motor dexterity were considered as dependent variables.

The Digit Symbol Substitution Test from the WAIS–III battery (Weschler, 1999) was employed as a measure of speed of processing (Salthouse, 1992; Brebion et al., 1998) to be covaried on statistical analyses. This test was included in the executive functions dimension on previous factor analysis. Since a variable should not be used as a covariate and a dependent variable at the same time, we chose to examine tests related to executive function independently. Span of Backward Digits Test (Weschler, 1999), Trail-Making Test Part B (TMT–B; Lezak, 1995) and a fluency test (FAS; Lezak, 1995) were used as representative of working memory and executive functions.

Verbal memory was assessed using the Rey Auditory Verbal Learning Test (RAVLT; Rey, 1964) immediate memory span, total learning, recall following short and long delay periods, and recognition. Motor dexterity was assessed using the grooved pegboard (both hands) and sustained attention/vigilance the Continuous Performance Test–Degraded Stimulus (CPT–DS; Cegalis & Bowlin, 1991) hits and reaction time and Brief Test of Attention (BTA; Schretlen et al., 1996). The vocabulary test from WAIS–III was used to control for premorbid IQ (Lezak, 1995).

DUI, duration of untreated illness; DUP, duration of untreated psychosis.
I. Total scores were calculated using sums of global scores of each symptom.

RESULTS

Sample

The socio-demographic and clinical characteristics of patients and controls are presented in Table 1. The two groups did not differ on age (t=0.63, d.f.=148, P=0.53) or gender distribution (χ²=3.07, P=0.08), although there was a trend-level difference. Patients and healthy controls differed in terms of years of education (t=−2.15, d.f.=148, P=0.03) and premorbid IQ (t=−2.27, d.f.=148, P=0.03). Therefore on the subsequent analysis, gender, years of education and premorbid IQ were always included as covariates.

There were no differences in socio-demographic and cognitive characteristics when patients with schizophrenia and with other psychoses were compared (data not shown).
These results suggest that speed of information processing may be a core cognitive deficit in schizophrenia and might mediate a broader diversity of cognitive disturbances.

Our results confirm and extend previous findings in chronic schizophrenia on the influence of speed of information processing on memory and working memory (Brebin et al., 1998, 2000; Hartman, 2002). We have also found that a more diverse range of cognitive functions, including attention, motor dexterity and executive functions, are also influenced by speed of processing, and that this is already evident during the early phases of the disease. It has been proposed that age-related cognitive decline might be associated with a decrease in the speed with which many processing operations can be executed and that this reduction leads to impairments in cognitive functioning (Salthouse, 1996).

Andreasen and colleagues (1998) proposed the cognitive dysmetria model in schizophrenia. This posits that a neural disconnection in cortical-cerebellar-thalamic-cortical circuitry in people with schizophrenia leads to an impairment in synchrony or the smooth coordination of mental processes. When synchrony is impaired, there is cognitive dysmetria, and the impairment in this basic cognitive process defines the phenotype of schizophrenia and produces its diversity of symptoms. We hypothesize that processing speed is one ‘candidate cognitive dysfunction’ that could explain the myriad symptoms of schizophrenia.

Neuroimaging studies in multiple sclerosis (Sanfilipo et al., 2006), stroke (Jokinen et al., 2005) and normal ageing (Gunning-Dixon & Raz, 2000) have demonstrated that deficits in speed of processing are associated with abnormalities in cerebral white matter. It is noteworthy that abnormalities in white matter have also been related to deficits in processing speed in schizophrenia (Antonova et al., 2005).

In accordance with the cognitive dysmetria hypothesis, a deficit in speed of processing in schizophrenia might reflect the disruption of neural activation transmission owing to white matter alteration. This might secondarily affect higher-order processing, leading to functional disturbances. Cognitive impairment in schizophrenia has great relevance for the evolution of the illness, especially the level of general functionality and autonomy that patients eventually achieve (Green, 1996). This emphasizes the potential value of addressing cognitive dysfunction as a primary target of therapeutic intervention. Cognitive remediation in schizophrenia has already proved to be valuable in terms of amelioration of problems with social functioning (Wykes et al., 2003). If our hypothesis proves to be true, pharmacological or neurorehabilitation-based therapeutic approaches aimed at remediating specific cognitive deficits (e.g. memory or executive functions) should take into account the effects of an impaired speed of information processing which might may be understood as a core cognitive deficit.

One of the limitations of this study might be the validity of the test used to measure speed of processing. Although the Digit Symbol Substitution Test has been traditionally used as a measure of processing speed (Salthouse, 1992, 1993; Lindenberger et al., 1993; Brebin et al., 1998), it might also be measuring a large
number of other cognitive processes. This limitation applies to most of the neuropsychological tasks and emphasises the need for more specific cognitive tasks for research purposes. A second limitation of this study is that patients had been treated prior to cognitive evaluation. Although treatment was minimal, antipsychotics might have produced changes in cognition. If medication had some particular significant effect on speed of information processing this might have biased the interpretation of our results. However, to our knowledge there are no reports of a specific effect of antipsychotics on speed of processing. Therefore, the significant relationship between cognitive functioning and processing speed is unlikely to be due to medication.

In conclusion, we suggest that speed of processing might be a core cognitive function in schizophrenia. Thus, cognitive deficits described in people with schizophrenia from the very early stages of the illness might be determined by a slower speed of information processing. Our findings provide further support for recent theories of a neural basis of schizophrenia, such as the cognitive dysmetria theory, and suggest new strategies for neurorehabilitation research.

ACKNOWLEDGEMENTS

We thank the PAFIP researchers who helped with data collection and during the investigations and the study participants and their families.

This study was performed under the grant support of: Instituto de Salud Carlos III, FIS 00/0305, 01/3129, PI020499 and SENV Fundacio Research Grant CI 2005-0308007, Fundacion Marques de Valdecilla A/02/07.
