Pernicious anaemia presenting as catatonia without signs of anaemia or macrocytosis

S. Jauhar, A. Blackett, P. Srirreddy and P. J. McKenna

Summary

Pernicious anaemia can present with psychiatric symptoms before haematological or neurological manifestations appear. We describe a young woman who presented with insidious onset catatonia without evidence of psychosis or depression. Blood count and mean cell volume were normal and neurological findings were equivocal. Low B₁₂ levels and intrinsic factor antibodies were found only by chance when they were included in a battery of further investigations. B₁₂ replacement was followed by prompt improvement. This case provides an argument for wider screening for B₁₂ deficiency in certain individuals with psychiatric disorders.

Declaration of interest

None.

Psychiatric disturbance was alluded to in Addison’s original description of pernicious anaemia, and nowadays the disorder is recognised as being associated with depression, mania, psychosis and dementia.1 It is also known that psychiatric symptoms can precede the onset of anaemia or neurological features and can sometimes be seen in the absence of macrocytosis.2 A case report has recently added catatonia to the list of psychiatric syndromes associated with B₁₂ deficiency.2 Here we present a further case, where catatonia was the presenting — and only — psychiatric feature of what turned out to be autoimmune B₁₂ deficiency. Haematological abnormality was absent and neurological abnormality was subtle to the point of being easy to dismiss.

Method

A 27-year-old single croupier and singer of mixed race was compulsorily admitted after she was found to be living in a flat with no heating and electricity. She had stopped working around a year previously and had become withdrawn. There was no previous medical or psychiatric history. In hospital she was noted to be unkempt and vague; she would often stare blankly into space, had no spontaneous interaction with others, and at times was doubly incontinent. However, no affective or psychotic symptoms were elicited. She was treated with olanzapine with slight improvement. She was discharged by a mental health tribunal and then became lost to follow-up. She was readmitted 6 months later, again in a state of self-neglect. She was very slow to initiate movements, took a long time to get out of bed, and would stand in the same position for long periods in the ward, often with her arms folded across her chest. She also followed members of staff around the ward repeating what they said. During an interview, she spent the whole time in a praying position. Her speech was reduced to greetings and giving answers to questions. She showed echolalia. Her affect was impassive and any changes of facial expression were few and slow. As previously, no psychotic or depressive symptoms could be elicited.

Neurological examination revealed a left palmomental reflex (fist–edge–palm) test. Cognitively, she scored 67/100 on the Wisconsin Card Sorting Test,5 which measures ability to inhibit prepotent responses (error score 43, scaled score 1), and the Brixton Test,6 a rule-shifting test conceptually similar to the Wisconsin Card Sorting Test (error score 39, scaled score 1). Computed tomography (CT) scan was reported as showing mild frontal atrophy, but according to further neuroradiological opinions this was not unequivocally outside the normal range (Fig. 1). Magnetic resonance imaging was reported as showing only increased cerebrospinal fluid spaces around the hemispheres and increased third ventricle size. Single photon emission tomography scan was normal. Electroencephalogram (EEG) showed only bilateral posterior theta wave activity.

Because of the inconclusiveness of these findings, one of the authors (S.J.) undertook a raft of further investigations, including autoantibody screen, thyroid function tests, syphilis serology, serum B₁₂ and folate, and voltage-gated potassium channel antibodies. The only abnormal finding was a low vitamin B₁₂ of 159 ng/l (normal range 189–883 ng/l). Around this time her haemoglobin was 12.7–13.1 g/dl on different occasions, with mean cell volume (MCV) of 86–94 fl (normal range 86–98 fl). Subsequently, antibodies to intrinsic factor were found, and the diagnosis of pernicious anaemia was made.

Results

Olanzapine, which had been recommenced shortly after admission (in addition to diazepam), did not result in obvious improvement over 4 weeks. However, less than 10 days after starting on hydroxycobalamine (intramuscularly, at a dosage of 1 mg on alternate days for 10 days), nursing staff commented on a marked improvement in her behaviour and self-care. Her Addenbrooke’s score (on parallel versions of the ACE–R) was 80/100 2 weeks after commencement of treatment and 90/100 4 weeks later. Digit span after 10 weeks of treatment was 6 forwards and 5 backwards and she had improved into the ‘moderate average’ range on the Brixton test (19 errors, scaled score 5); however, she remained in the impaired range on the Hayling Test (33 errors, scaled score 1). As she began to talk more, she described having had pins and needles in her hands and feet for approximately a year, which could have reflected spinal cord demyelination. No abnormalities were found on repeat neurological examination. A repeat CT scan 4 months after institution of B₁₂ replacement continued to show much the same degree of frontal sulcal widening, but was reported as normal.

She discontinued olanzapine 2 months after discharge from hospital. Four months later, after a 2-week delay in administration of her hydroxycobalamine injection, she had a brief, 2-week
B12 deficiency can cause cognitive impairment up to and including dementia;¹ the degree to which this improves with B12 replacement is variable, with 1 year having been suggested as a watershed for reversibility.² This person’s lack of anaemia and her (at most) subtle neurological signs meant that vitamin B₁₂ deficiency was not originally screened for. In 1988, Lindenbaum et al questioned the existing orthodoxy that B₁₂ deficiency only presented with neurological disorder when anaemia was also present.³ They reviewed 141 people who were given a final diagnosis of clinical B₁₂–deficiency causing isolated and partially reversible neurocognitive dysfunction and found that 40 (28%) had either no anaemia or no macrocytosis at initial presentation, and that in 19 (13%) both haematological indices were normal. Six further individuals had anaemia, but with an MCV that was normal or low (in four of these there were independent causes for this). In some of these people diagnosis was delayed for several months or years.

This woman’s case adds to the literature documenting the occurrence of catatonia in a wide range of systemic diseases, and supports the view that it is an independent psychiatric entity, not one that develops only in the context of a schizophrenic or affective syndrome.⁴ It also provides an argument that vitamin B₁₂ deficiency should be considered in any person with an unusual psychiatric presentation, not only when this is ‘organic’, and regardless of the absence of macrocytosis or anaemia. This is particularly important since delayed diagnosis can be associated with lack of reversibility.

Discussion

This individual presented with marked social decline, self-neglect and later developed full-blown catatonic symptoms without evidence of psychotic or affective symptoms. Her neurological abnormalities were minimal, and whether there was any abnormality on brain imaging became the subject of debate among the clinicians and neuroradiologists involved in her case. Olanzapine brought about no improvement over 4 weeks but after olanzapine and recovery after this drug was re-introduced. Two episodes of catatonia, which resolved promptly to re-initiation of olanzapine. Currently, she is continuing to receive olanzapine and vitamin B₁₂ injections, is out of hospital, lives independently in her own flat and is planning to enrol in a music course.
