Oestrogen receptor polymorphisms and late-life depression

Joanne Ryan, Jacqueline Scali, Isabelle Carrière, Karine Peres, Olivier Rouaud, Pierre-Yves Scarabin, Karen Ritchie and Marie-Laure Ancelin

Background
Evidence suggests a role for oestrogen in depression but the involvement of oestrogen receptor polymorphisms remains unknown.

Aims
To determine the association between oestrogen receptor polymorphisms and late-life depression and the modifying effect of hormone treatment.

Method
Depression was assessed using the Mini-International Neuropsychiatric Interview, according to DSM-IV criteria and the Centre for Epidemiologic Studies – Depression Scale. The association between oestrogen receptor α and β (ER-α and ER-β) polymorphisms with severe depression was examined in 6017 community-dwelling elderly people using multivariate logistic regression.

Results
In women, the ER-α rs2234693 and rs9340799 polymorphisms were significantly associated with the risk of late-life depression. The A allele of ER-β rs1256049 increased the risk of depression, but only for non-current users of hormone treatment. In men, only the ER-β rs4986938 polymorphism showed a weak association with depression risk.

Conclusions
Oestrogen receptor polymorphisms are associated with severe late-life depression risk in women only.

Declaration of interest
None.

Depression is a major public health problem with high prevalence rates worldwide and an increased risk of comorbidity and mortality, especially in elderly people. Family studies have provided evidence that there is a genetic component to depressive disorders, although only a small number of candidate genes have been identified.1 Several lines of evidence suggest a role for oestrogen in depression. Depression results from a disruption in normal brain neurochemistry, including depletion in the levels of serotonin, and oestrogen has been shown to modulate neurotransmitter turnover and enhance serotonergic activity.2 Numerous epidemiological studies support these observations, linking oestrogen with depressed mood and antidepressant response (see Ancelin et al for a review).1 Oestrogen-containing hormone treatment is also effective in improving the depressed mood of perimenopausal women,3 although its use in older postmenopausal women remains more controversial. However, given that the actions of oestrogen occur in large part through intracellular activation of oestrogen receptors (ER-α and ER-β), it is surprising that very few studies have examined whether oestrogen receptor polymorphisms can modify the risk of depression. Polymorphisms of these receptors have been associated previously, although not consistently, with oestriadiol levels,4 vasomotor symptoms5 and other brain disorders such as Alzheimer’s disease.6,7 Genetic variation in oestrogen receptors may also influence a person’s susceptibility to developing depression and may modify oestrogen signalling and thus the effect of hormone treatment on mood, but this has not been examined previously. This current study aimed to investigate the association between severe late-life depression and five ER-α and ER-β polymorphisms. Given the lack of data in this field, we did not hypothesise which genotypes would be most frequent in participants with depression. Analysis was stratified by gender so that individual associations in men and women could be identified, and the potential modifying effect of hormone treatment use in women could be evaluated.
oestradiol levels. 20 These are: ER-
mineral density, 17,18 breast cancer, 19 vasomotor symptoms 6 and
kit, Qiagen, France) and stored at

Oestrogen receptor polymorphisms

For Men

Five SNPs were examined that have shown potential causal
associations with diseases and other hormone-related health
outcomes in some previous studies, including Alzheimer’s
disease,7,8 cognitive function,14 cardiovascular disease,15,16 bone
mineral density,17,18 breast cancer,19 vasomotor symptoms4 and
osteriadiol levels.20 These are: ER-α rs2234693 (otherwise known as
PvuII) and rs9340799 (XbaI), ER-β rs1256049 (AluI),
rs4986938 (RsaI) and rs1271572 (in the promoter region of the
gene).

Other measures

When participants joined the study, information was obtained on
sociodemographic and lifestyle characteristics, as well as overall
health. Body mass index (BMI) was calculated as weight (kg)
divided by the height squared (m²). Participants unable to
complete at least two tasks from either the Instrumental Activities
of Daily Living (IADL)21 or the Activities of Daily Living (ADL)22
scales, were classified as having physical limitations. Cognitive
impairment was defined as having a Mini-Mental State
Examination (MMSE)23 score of less than 26 and questionnaires
concerning sleeping habits were used to define insomnia.24
Current use of hormone treatment at the time of the baseline
interview was validated by presentation of the prescription or the
medication itself.

Information on the participant’s health was obtained through
detailed medical questionnaires, a complete inventory of all drugs
used within the preceding month and from fasting blood samples.
These questionnaires included their history of vascular diseases
(angiography, myocardial infarction, stroke, cardiovascular
surgery, bradycardia or palpitations), other chronic illnesses
(asthma, diabetes (fasting glucose ≥7.0 mmol/l or reported
treatment), hypercholesterolemia (total cholesterol ≥6.2 mmol/l),
hypertension (resting blood pressure ≥160/95 mmHg or
treated) and thyroid problems) or cancer diagnosis within the
previous 2 years. Participants were classified as having
comorbidity if they suffered from vascular disease, more than
one chronic illness or a recent cancer.

Statistical analysis

A χ² test was used to compare the observed allele frequencies with
those expected under the Hardy–Weinberg equilibrium. The
assumption between baseline sociodemographic and clinical
variables with both depression and oestrogen receptor poly-
morphisms was examined using t-tests, ANOVA and χ² tests. Due
to the statistically significant interactions between gender
and depression, all subsequent analyses were undertaken
separately for males and females. Genotype frequencies of the
oestrogen receptor polymorphisms were compared for
participants with depression and those without using logistic
regression models. Adjustment was made for covariates that were
significantly associated with depression in this sample and that
remained significant in the final multivariate models. The
potential interaction between oestrogen receptor polymorphisms
and the use of oestrogen-containing hormone treatment in
women was also considered, based on our a priori hypothesis that
oestrogen receptor polymorphisms could mediate the effect of
oestrogen on depression. There was no indication of collinearity
between the covariates in the adjusted models. We used SAS
version 9.1 for Windows for all of the analyses and all tests were
two-tailed, with a significance level of P < 0.05.

Results

Participants’ characteristics

Baseline characteristics of the 6017 participants are summarised in
Table 1. They ranged in age from 65 to 96 years with a mean of 73
years. Men and women differed significantly on all socio-
demographic and health variables examined, with the exception
of age. Women were significantly more likely to use anti-
depressants, to have current depressive symptoms and to have a
current or previous diagnosis of major depressive disorder (Table 1).
Overall, 564 participants were diagnosed with current severe
depression (CES-D ≥ 23 or current major depressive disorder),
with a higher prevalence rate in women compared with men
(12.9% v. 4.4% respectively, χ²1 = 123, P < 0.001).

Polymorphism frequencies according
to depression status

The overall distribution of genotypes in both genders was not
significantly different from those predicted by the Hardy–
Weinberg equilibrium, except in the case of the ER-α rs1271572
polymorphism in women (χ²1 = 5.7, P = 0.02). The ER-α
polymorphisms are known to be in strong linkage disequilibrium
with one another,16 as are the three ER-β polymorphisms
examined.16 Genotype frequencies for each of the oestrogen
receptors according to the participant’s depression status are given
in Table 2. There was no significant difference in the genotype
distribution between men and women, although women were
more likely to be heterozygous for ER-β rs4986938 (49.6% of
women overall had the GA genotype compared with 46.6% of
men, χ²2 = 5.7, P = 0.06). For both genders, the frequency of the
AA genotype for ER-β rs1256049 was very small so these
participants were grouped with those heterozygous GA for
subsequent analysis.

Oestrogen receptor polymorphisms and depression

The results of the multivariate logistic regression analyses for the
associations between oestrogen receptor polymorphisms and
depression are shown in Table 3. In men the only borderline
significant association was a 1.7 times increase in current severe
depression with the AA versus the GG genotype of ER-β
rs4986938. None of the other polymorphisms showed any
significant association with depression in men.
Among women however, those homozygous CC for the ER-α rs2234693 polymorphism were 40% less likely to have current severe depression compared with homozygous TT women. The findings concerning the rs9340799 polymorphism were almost identical, with women having the GG genotype significantly less likely to have late-life depression compared with women with the AA genotype. In terms of the ER-β, women with at least one A allele of the rs1256049 polymorphism were more likely to

ER-α, oestrogen receptor α; ER-β, oestrogen receptor β.
have current severe depression, but this was at the limit of statistical significance. The other two ER-β polymorphisms were not associated with late-life depression.

### Oestrogen receptor x hormone treatment interaction

When the potential modifying effect of hormone treatment use on the association between these oestrogen receptor polymorphisms and severe depression in women was examined, there was a non-significant trend for an interaction between ER-β rs1256049 and current hormone treatment (interaction term, $P = 0.08$ in the multivariate adjusted model shown in Table 3). Subsequent analysis stratified by current hormone treatment use revealed that women who were not using treatment ($n = 2986$) were significantly more likely to have current severe depression with the GA/AA genotype (odds ratio (OR) = 1.72, 95% CI 1.17–2.50, $P = 0.005$). In stark contrast, among women who were using hormone treatment ($n = 539$), the GA/AA genotype was not associated with the risk of severe depression (OR = 0.69, 95% CI 0.23–2.08, $P = 0.51$).

### Discussion

In this older population-based cohort, we have found significant gender-specific associations between polymorphisms of ER-α and ER-β with severe late-life depression. The results also provide some evidence of an interaction between hormone treatment and one of the ER-β polymorphisms, which modified a woman's risk of depression.

### Association between ER-α polymorphisms and severe depression in women

Of the few previous studies that have investigated the association between depression and ER-α polymorphisms in women, the results have been mixed, and this may relate to differences in study sizes (smaller studies may lack statistical power), and populations (e.g. age, menopausal status, hormone treatment use), as well as the criteria for depressive symptomatology. The SWAN study of 1338 pre- and perimenopausal women from four different ethnic groups and the Rotterdam study of 2468 elderly women, have both reported no significant association between the rs2234693 and rs9340799 polymorphisms and moderate depressive symptoms (CES-D $\geq 16$). In two small studies of young postmenopausal women, differential findings have been reported in unadjusted analysis. No association was found between these same ER-α polymorphisms and depressed mood in 177 Mexican women, yet significant associations were found in a study of 106 Korean women. The only previous study to examine the association between oestrogen receptor polymorphisms and major depressive disorder (based on the Hamilton Scale and DSM-IV criteria) reported that the frequency of the rs2234693 CC genotype was significantly higher in 126 midlife Chinese women with depression (mean age 46.7 years) than in the 89 controls. In our larger study of 3525 elderly women however, the CC and GG genotypes of the rs2234693 and rs9340799 polymorphisms respectively were associated with a significant decrease in current severe depression (defined as a current major depressive disorder based on DSM-IV criteria or severe depressive symptoms using a CES-D score of 23 or greater). In post hoc analysis we did not find a significant association with these ER-α polymorphisms and moderate depressive symptoms alone (CES-D $\geq 16$, see online Table DS1). Our findings thus relate specifically to a severe clinical level of current depression.

### Potential interaction between ER-β polymorphism and hormone treatment

The association between ER-β and depression has been insufficiently studied. There is one report of a non-significant association between another polymorphism (rs1256030) and moderate depressive symptoms (CES-D $\geq 16$) in 1435 midlife women, and in a Korean study of 43 women with postmenopausal depression and 63 controls no significant association was found.
with rs1256049 or rs4986938. In our study we find that the ER-β rs1256049 polymorphism was significantly associated with an increased likelihood of severe depression in women, but only for those who were non-hormone treatment users. No significant association was observed for women who were currently using hormone treatment. It has been shown previously that oestrogen receptor polymorphisms and hormone treatment can interact to influence health outcomes in women. To our knowledge, however, no study has examined whether such an interaction can modify the risk of depression, despite several randomised controlled trials demonstrating the psycho-protective effects of hormone treatment. Our finding provides some preliminary evidence that hormone treatment could be beneficial for certain genetically vulnerable women, by reducing the risk of depression associated with the ER-β rs1256049 polymorphism.

Oestrogen receptor polymorphisms and depression in men

We found no significant association between ER-α polymorphisms and moderate or severe depression in men (Table 3), in a similar manner with bone density and fractures conducted. The rs2234693 and rs9340799 polymorphisms have not associated with major depressive disorder in a small case–control study of middle-aged Chinese men nor in the Rotterdam study of depressive symptoms. Neither of these studies, however, examined associations with ER-β. We report here that the AA allele of the ER-β rs4986938 may increase the likelihood of depression specifically in men, although this was of borderline significance. In a similar manner, one of the few prior studies examining this polymorphism reported a higher frequency of the A allele in men with Alzheimer’s disease, but no such association in women.

Biological hypothesis linking oestrogen receptors and depression

The two oestrogen receptors, ER-α and ER-β, classically function as lipid-activated transcription factors and can affect hundreds of genes, including regulation of the synthesis and metabolism of various neurotransmitters in the brain. The mechanisms by which oestrogen receptors could influence depression are thus complex. It remains uncertain what precise effects the polymorphisms examined here may have on receptor expression. Although silent mutations, they can still affect messenger RNA structure, stability and receptor synthesis, and thus have potentially important functional consequences. At least in terms of rs2234693 and rs9340799, they have been shown to regulate the expression of ER-α and they may alter transcription factor binding. These polymorphisms may also be in linkage disequilibrium with other functional polymorphisms that have not yet been identified. The ER-α polymorphisms examined in our study have been associated with other brain disorders, such as cognitive decline and Alzheimer’s disease, although not consistently. These polymorphisms have also shown significant associations with oestradiol levels in postmenopausal women (lower oestradiol with the T (rs2234693) and A (rs9340799) alleles), and in a similar manner with bone density and fractures (higher bone mass density and lower fractures for the rs9340799 genotype GG) (see Ioannidis et al for meta-analysis). This would support earlier findings that oestrogen may have a protective effect against depression.

Our data suggest distinct genetic vulnerability to depression for men and women. Different polymorphisms of ER-β increased the likelihood of severe depression in men and women, whereas in women, only ER-α polymorphisms were associated with late-life depression. There are numerous mechanisms that could help explain these gender differences (see Gillies & McArthur for review). Although males and females have a similar distribution of ER-α and ER-β in the brain, there appear to be differences in the level of expression of these receptors in various regions. Our results may partly account for gender differences in depression prevalence and highlight the need for a gender-specific approach to the development of novel hormone-based therapies.

Study limitations and strengths

Limitations to this study include the relatively low response rate, which limits the ability to generalise these findings as study volunteers tend to be better educated and healthier than the overall population. Participants diagnosed with probable/possible dementia at inclusion (n = 217) were excluded from this analysis to minimise recall bias. However, as such individuals may also have higher rates of depressive symptoms this could have decreased the overall power of the study, possibly underestimating the associations found. Possible prescription bias in relation to women who are given hormone treatment should also be taken into account, although we have controlled for numerous potential confounding factors in the analysis. The results of this analysis were not adjusted for multicomparisons, as there was a strong a priori biological rationale for investigating these five specific associations, given the extensive scientific literature supporting a role for oestrogen in depression. The usefulness of a Bonferroni correction in this study is thus questionable and would result in an inflated type 2 error rate, especially given that the correction assumes independence of the tests, but both ER-α polymorphisms are in strong linkage disequilibrium, as are the three ER-β polymorphisms. It remains likely, however, that based on the 5% significance level, one of the significant associations found occurred merely by chance. Finally, it should be noted that in this study we report associations between oestrogen receptor polymorphisms and the prevalence of late-life depression, but have not differentiated the independent associations with depression incidence and disease duration.

This study is strengthened by its sample size and population-based design, as well as the inclusion of both men and women to enable the assessment of independent gender-specific associations. Depression was assessed by trained staff using two distinct measures, including a structured diagnostic interview, which have been validated in the general population. Severity ratings allowed us to examine separately the relationship between moderate depressive symptoms and severe depression, with oestrogen receptor genotypes. Although our analyses have adjusted for a large range of sociodemographic and health variables, including previous depressive episodes, it is still possible that there are unrecognised factors that could help explain our findings. Replication of our findings in other large population-based studies is needed.

We report here that polymorphisms of ER-α in particular are associated with depression in older women. In addition, there was some evidence that current hormone treatment modified the association between ER-β rs1256049 and severe depression in women. These findings suggest the possibility that some women may be genetically more susceptible than others to the psycho-protective effects of hormone treatment. This could have important clinical applications, suggesting the potential for offering tailored hormonal therapies based on genetic markers for the treatment of mood disorders in women, and perhaps men, via the development of oestrogen-receptor selective effectors.
