Suicide and religion†

Christopher C. H. Cook

Summary
Much of the evidence that religion provides a protective factor against completed suicide comes from cross-sectional studies. This issue of the Journal includes a report of a new prospective study. An understanding of the relationship between spirituality, religion and suicide is important in assessing and caring for those at risk.

Suicide is one of the major causes of mortality in the young and the elderly and a College Report has identified suicide prevention as a priority for public health policy in the UK.1 Attitudes towards suicide have generally been negative among all of the world’s major faith traditions, albeit mental disorder is usually understood as a mitigating ethical factor. On the one hand this has in the past led to unsympathetic and harsh responses, and a sense of shame for victims and their families, but it has also long been considered a reason why religious people might be less likely to take their own life.

Research
Although there is much empirical research to support the view that religion is protective against suicide, and some contrary evidence, there have been few prospective studies. According to Koenig et al,2 out of 141 studies on religion and suicide conducted to date, only two3,4 were prospective or longitudinal. One of these studies comprised a retrospective trawl of a national mortality database, and the other (which was not originally designed for the purpose of studying the influence of religion on suicide) did not study completed suicides. Indeed, as Koenig et al note, the design of prospective studies of completed suicide is challenging, requiring large sample sizes and prolonged periods of follow-up to ensure sufficient numbers of observed suicides.

The publication in this issue of the Journal of the first prospective study of religious service attendance and completed suicide is therefore significant. Based on the Third National Health and Nutrition Examination Survey (NHANES III) in the USA, Kleiman & Liu have shown that those who frequently attended religious services (i.e. ≥24 times per year) were less than half as likely to die by suicide than those who attended services less frequently.5 Following more than 20,000 participants over 12–18 years, 25 individuals were identified as having died by suicide, slightly fewer than might have been expected on the basis of national statistics. Given this small number of actual suicides, sample power in this study is somewhat more modest than one might have expected. It must also be noted that this data-set was not constructed for the purpose at hand and we know nothing about the specific religious affiliations, experiences, beliefs or other religious behaviours of participants – only the frequency with which they attended religious services. Notwithstanding these limitations, this is a significant piece of research, and the authors conclude that frequent religious service attendance is a long-term protective factor against suicide.

How might religion help?

There is evidence to suggest that religion may help people to cope better with life stresses, reduce the incidence of depression and substance misuse, facilitate recovery from depression, enhance social support and provide sources of hope and meaning (pp. 179–180).2 Any or all of these considerations provide possible explanations for the putative protective benefit identified in the study by Kleiman & Liu. Although interpretations of such studies are debated,6 and negative findings are also reported (e.g. King et al7), the overall balance of findings is thought by many to reveal a benefit for religious beliefs and practices in relation to mental health and well-being.

In an ideal research design, we would know about more than simply religious service attendance. Although the data available to Kleiman & Liu are an improvement on the crude measures of religion employed in the only two previous prospective studies of completed suicide, and although religious service attendance is an objective measure widely employed in research of this kind, it is frustrating not to know more about the religious beliefs, behaviours, experiences and traditions of these participants. However, what we do know is not unimportant. Whatever kinds of religious services these individuals attended, we know that the teachings and traditions to which they were exposed would have had particular implications for anyone contemplating suicide.

Religious teachings on suicide

In Hebrew scripture, suicide is implicitly condemned in the commandment not to commit murder (Exodus 20:13) and both Jewish and Christian commentators have generally seen suicide to be forbidden by this commandment. Augustine of Hippo, for example, argued that the commandment is not qualified (it does not say ‘You shall not murder your neighbour’ but simply ‘You shall not murder’), that no scriptural permission to die by suicide is granted, and that it is better for the Christian to suffer than to

condemned in Judeo-Christian scripture, and attitudes have been in contrast, it has been noted that suicide is not explicitly a behaviour. It might be expected that they attend religious services less frequently, but this group almost certainly includes some frequent service attenders (e.g. among those who espouse more modern styles of worship and who eschew traditional services less frequently, but this group almost certainly includes some frequent service attenders (e.g. among those who espouse more modern styles of worship and who eschew traditional understandings of ‘religion’).

As a result, suicide is illegal in many Islamic countries, and it has been suggested that suicide is under-reported in the Islamic world.

In Eastern faith traditions, attitudes towards suicide may be understood as more ambiguous, and Durkheim took Hinduism as a religion within which examples of altruistic suicide might be identified, but the general sense of respect for life, and concerns about the impact on karma, still provide a prevailing understanding that suicide is wrong.

Although the study by Kleiman & Liu does not address the situation of those who would describe themselves as ‘spiritual but not religious’, it is possible that this group do not experience protection against either depressive disorder or suicidal behaviour. It might be expected that they attend religious services less frequently, but this group almost certainly includes some frequent service attenders (e.g. among those who espouse more modern styles of worship and who eschew traditional understandings of ‘religion’).

The Qur’an is more explicit in its injunction against suicide:

Nor kill (or destroy) yourselves: for verily Allah hath been to you Most Merciful.

Surah 4:29 (p. 2055)

As a result, suicide is illegal in many Islamic countries, and it has been suggested that suicide is under-reported in the Islamic world.

It might be expected that they attend religious services less frequently, but this group almost certainly includes some frequent service attenders (e.g. among those who espouse more modern styles of worship and who eschew traditional understandings of ‘religion’).

The findings of Kleiman & Liu add to the already large body of evidence obtained from cross-sectional studies, the great majority of which show lower levels of suicidal ideation and behaviour among those who are religious. It would therefore seem wise to take religion into account when assessing suicidal risk, albeit remembering that religion is no guarantee against suicide (as the study by Kleiman & Liu clearly demonstrates). Although this is something that merits discussion with patients at risk of suicide, Koenig et al. rightly note (p. 190) that caution should be displayed if considering spiritual/religious interventions with such a group, as no studies to date have examined effectiveness (or harm) of such interventions. This therefore again raises the question of whether and how boundaries can be drawn in psychiatry in such a way as to define what may properly be discussed, and when, and how, in relation to spirituality and religion.

The College Position Statement, Recommendations for Psychiatrists on Spirituality and Religion, suggests some of the general ways in which we might seek to ensure good practice, but it is also clear that much is properly left to the judgement of the psychiatrist and that patients contemplating suicide are especially vulnerable.
