Dopamine transporter occupancy by methylphenidate and impulsivity in adult ADHD

Cleo L. Crunelle, Wim van den Brink, Geert Dom and Jan Booij

Summary
Impulsivity is a multidimensional construct, including impulsive decision-making and impulsive action, representing relatively independent neurocircuitries. ADHD is treated with methylphenidate, a drug that binds to dopamine transporters. This study in 24 adult male patients with ADHD shows that dopamine transporter occupancy by methylphenidate in the putamen correlates with improvements in cognitive but not in motor impulsivity.

Declaration of interest
W.v.d.B. received fees from Eli Lilly unrelated to the present work. G.D. received fees from Lundbeck, Janssen Pharmaceuticals and Eli Lilly unrelated to the present work. J.B. has received consultancy payments from GE Healthcare.

Method
A total of 24 male medication-naive adult patients with ADHD were included in the study. Recruitment, diagnosis and inclusion/exclusion criteria are described elsewhere (trial registered with Nederlands Trial Register, NTR3127). Eight patients had a comorbid diagnosis of cocaine dependence and were abstinent for >2 weeks prior to inclusion and no other psychiatric comorbidities were present. Striatal dopamine transporter availability and impulsivity levels were assessed at baseline (before medication) and after a 2-week treatment with extended-release methylphenidate (MPH-OROS 54 mg). Dopamine transporter availability (BPND) was assessed on a brain-dedicated single-photon emission computed tomography system using the caudate and putamen as regions of interest. A structural magnetic resonance imaging scan was made of each patient for co-registration. On the last treatment day, BPND was assessed 5 h after supervised intake of the last methylphenidate tablet and dopamine transporter occupancy by methylphenidate was calculated as previously described. Cognitive and motor impulsivity were assessed using a delayed discounting task and a stop-signal task respectively. The outcome measures were the discounting rate k as a measure of cognitive impulsivity (where higher k values represent higher cognitive impulsivity) and the Stop Signal Reaction Time (SSRT) as a measure of speed of inhibition to assess motor impulsivity.

Results
Our entire sample was male, 34 (s.d. = 6) years old, had a mean of 10 (s.d. = 4) years of education and an IQ of 105 (s.d. = 5). Body mass index was 26 kg/m² (s.d. = 4). One patient was diagnosed with the hyperactive ADHD subtype, 10 with the inattentive subtype and 13 with combined ADHD subtype. Patients had a mean ADHD Symptom Rating Scale score of 12 (s.d. = 4), indicating substantial severity of ADHD symptoms. Eleven patients were smokers and had a nicotine dependency score of 5 (s.d. = 2) on the Fagerström Test for Nicotine Dependence. Patients scored 82 (s.d. = 13) on the Barratt Impulsiveness Scale, indicating substantial impulsivity.

Following methylphenidate, BPND decreased with 33% (s.d. = 16) and 41% (s.d. = 12) in the putamen and caudate nucleus respectively, indicating substantial dopamine transporter occupancy by methylphenidate. Following methylphenidate treatment, the discounting rate k decreased significantly (t = −2.31; d.f. = 23; P = 0.023) and this decrease correlated significantly with dopamine transporter occupancy by methylphenidate in the putamen (B = 618.71; t = 2.98; P = 0.010), but not in the caudate (P = 0.460; not significant). The SSRT also decreased significantly following methylphenidate treatment (t = −2.46; d.f. = 23; P = 0.023), but changes were not correlated with dopamine transporter occupancy by methylphenidate in putamen or caudate (both P > 0.389; not significant). In an

Impulsivity, a key symptom and characteristic of attention-deficit hyperactivity disorder (ADHD), is a multifactorial construct including motor impulsivity and cognitive impulsivity. Although motor and hyperactivity symptoms seem to decline with progression into adulthood, cognitive impulsivity (i.e. impulsive decision-making) remains prominent in adult ADHD and is associated with a range of clinical consequences (e.g. poor relational or professional stability). A recent study reported that impulsivity was positively associated with the availability of striatal dopamine transporters, although this was not replicated in a larger study. In adults with ADHD, increased dopamine transporter availability was observed, but a recent meta-analysis suggested that this increase was driven by patients that were previously medicated. Methylphenidate – widely prescribed for the treatment of childhood ADHD but more debated as to its use in adult populations – binds to dopamine transporters and reduces symptoms of ADHD. However, there is no direct evidence that dopamine transporter occupancy by methylphenidate is associated with a reduction of impulsivity symptoms in the cognitive and/or motor domains of impulsivity. In this study, we investigated whether striatal dopamine transporter occupancy by methylphenidate is related to improvements in the distinct domains of cognitive and motor impulsivity.
exploratory analysis, we found that the correlation of dopamine transporter occupancy by methylphenidate with the discounting rate \( k \) (in the putamen) was stronger in patients without cocaine dependence \( (B = 4435.27; t = 4.38; P = 0.001) \) than in those with cocaine dependence \( (B = 495.23; t = 2.53; P = 0.045) \). No other correlations were observed between dopamine transporter occupancy by methylphenidate in putamen/caudate nucleus with cognitive or motor impulsivity measures for subgroups of patients with or without cocaine dependence (all \( P > 0.267 \); not significant).

**Discussion**

This report provides preliminary evidence that dopamine transporter occupancy by methylphenidate in the putamen drives improvements in cognitive impulsivity in male adult patients with ADHD, i.e. that a higher occupancy of dopamine transporters by methylphenidate leads to better cognitive impulsivity. In contrast, motor impulsivity was not correlated with dopamine transporter occupancy by methylphenidate in putamen or caudate. Although the putamen is traditionally associated with the ‘motor loop’ of the corticobasal ganglia-thalamic circuit, more recent studies also suggest a role of the putamen in salience pathways (i.e. orbitofrontal cortex, insula, anterior cingulate gyrus), especially in patients with ADHD.\(^1,14\)

Yu suggested an additional pathway within patients with ADHD connecting left insula and left anterior cingulate gyrus via frontal gyrus and putamen.\(^14\) Through this pathway, changes in putamen function may modulate salience behaviour, including delay discounting. Our findings are in line with this hypothesis, but clearly need replication.

In previous studies in adult ADHD, dopamine transporter occupancy by methylphenidate \((3 \times 5 \text{mg})\) ranges between 29 and 51\%,\(^15\) with wide variability in dopamine transporter occupancy from one dose. One explanation for this variability may be differences in body weight between participants, while the methylphenidate dose was not weight-corrected. However, *post hoc*, we did not find a statistically significant association between body weight and dopamine transporter occupancy \((P > 0.115)\). It is also likely that there will be differences between patients in the rate they can metabolise methylphenidate (fast vs. slow). Also, previous ADHD treatments as well as the severity of ADHD symptoms may lead to conformational changes in the dopamine transporter, and consequently to changes in dopamine transporter occupancy by methylphenidate. Further studies may test these postulates.

Clinically, deficits in cognitive impulsivity have devastating effects on a patient’s life choices (i.e. risk-taking) and life quality. Our data suggest a benefit of methylphenidate specifically on these impulsivity choice mechanisms in adult patients with ADHD. These findings, although in need of replication, provide a new element in unrelated, aspects of impulsivity.\(^1\) The main limitation of this study is the small sample size. Future studies should investigate whether methylphenidate treatment correlates with improved functional connectivity linking striatal and frontal brain regions (e.g. using functional magnetic resonance imaging) and whether these findings can be validated in larger (ADHD clinical and non-clinical) populations.
