Vocational rehabilitation in early psychosis: cluster randomised trial

Tom Craig, Geoff Shepherd, Miles Rinaldi, Jo Smith, Sarah Carr, Fay Preston and Swaran Singh

Background
Individual placement and support (IPS) is effective in helping patients return to work but is poorly implemented because of clinical ambivalence and fears of relapse.15,16 Our primary hypothesis was that participants from the teams using motivational interviewing who found employment would have longer job tenure.

Aims
To assess whether a motivational intervention (motivational interviewing) directed at clinical staff to address ambivalence about employment improved patients’ occupational outcomes.

Method
Two of four early intervention teams that already provided IPS were randomised to receive motivational interviewing training for clinicians, focused on attitudinal barriers to employment. The trial was registered with the International Standard Randomised Controlled Trial Register (ISRCTN71943786).

Results
Of 300 eligible participants, 159 consented to the research.

Unemployment is common in young people recovering from a first episode of psychosis,1–3 although many still aspire to return to paid employment.4–6 Of the various methods of vocational rehabilitation, the strongest evidence base is found for individual placement and support (IPS), which involves rapid job search combined with minimal pre-vocational preparation and ongoing support.7,8 However, the majority of studies have involved highly motivated participants, who signed up not only for employment but also to take part in research,9 and translation into routine clinical care has often proved difficult,10 frequently because of the attitudes of key clinicians who discourage a return to work through a fear that the demands of employment might precipitate relapse.11,12 We therefore aimed to determine the feasibility, acceptability and effectiveness of combining IPS with training staff in early intervention teams in ‘motivational interviewing’ strategies. These aim to address anxiety about employment through a directive, client centred counselling style . . . helping clients to explore and resolve ambivalence’ (p.326).13 There are over 150 controlled trials demonstrating the value of motivational interviewing in a variety of settings in health and social care,14 and these techniques are now beginning to be employed in mental health services, particularly to address motivational conflicts with regard to medication adherence.15,16 Our primary hypothesis was that at 12 months a greater percentage of young people treated by early intervention teams that had staff trained in both IPS and motivational interviewing would achieve open employment compared with those in teams providing IPS only. A secondary hypothesis was that participants from the teams using motivational interviewing who found employment would have longer job tenure.

Clinical teams
The characteristics of the four teams were as follows. London 1 served an inner-city area with an average index of deprivation score of 34.9 (a high score, ranking the area 19 out of the 354 boroughs in England) and a 10% unemployment rate at the start of the study. London 2 served a mixed urban/suburban population with an average index of deprivation of 20.3 (ranking 144 out of 354 boroughs) and an average unemployment rate of 5%. Midlands 1 served an inner-city population with an average index of deprivation of 38.7 (ranked 10 out of 354 local authorities in England) with approximately 8% of the
tenure was also recorded (number of days in this employment). Open employment was the primary outcome.

The primary outcome was the proportion of young people in open employment at 12-month follow-up. Open employment was defined as having a job paying at least the minimum wage in a mainstream setting and not specifically for people with disability. Tenure was also recorded (number of days in this employment).

Participants

Patients were eligible for inclusion in the study if they were aged 18–35 years, not currently in work (i.e. part-time or whole-time mainstream employment) or full-time education but with the legal right to employment in England, and expected to remain under the care of the early intervention service for at least the subsequent 12 months (the early intervention services in this study provided care for a period of 2–3 years following a first episode, at the end of which patients needing continued specialist supervision were transferred to other non-early intervention community mental health teams). They also needed to be capable of giving written informed consent to the research. There was no requirement that they be particularly motivated to return to work or study.

Interventions

To minimise variation in practice regarding vocational interventions, the vocational specialists in the teams were trained to deliver IPS with fidelity to the published research instruments.17 They were also provided with written practice guidelines and support by M.R. who had previous experience with a fidelity-based approach in a large international trial.18 Care coordinators in the two teams that were randomised to receive the motivational interviewing training were provided with this training by recognised experts. The training comprised a 3-day course, followed by two further sessions over the next 3 months. A 2-day ‘refresher’ course was provided in the second year of recruitment. The training aimed to provide clinicians with a clear understanding of issues such as intrinsic motivation, ambivalence and readiness to change, as well as how to influence conversations, recognise appropriate times to use motivational interviewing and feel confident in the use of motivational interviewing in everyday practice. Training days consisted of brief didactic work, discussion, role-play and recorded demonstrations. Later sessions focused on discussion of cases. Although the training was directed at care coordinators and vocational specialists, other clinical staff in the teams were encouraged to take part. Research ethics approval was obtained through the Charing Cross research ethics committee.

Measures

The primary outcome was the proportion of young people in open paid employment at 12-month follow-up. Open employment was defined as having a job paying at least the minimum wage in a mainstream setting and not specifically for people with disability. Tenure was also recorded (number of days in this employment). Information on occupational activity was obtained from the young people themselves, from the clinical record and in two instances from family sources (where consent was given). Baseline information was also collected relating to sociodemographic variables and previous educational and employment history. All participants were asked to score their desire to return to work and their belief that this could be achieved in the near future separately on Likert scales scored from 0 (no desire/impossible) to 10 (maximum desire/strong conviction they would succeed). Clinical status was recorded at entry to the study and at follow-up using the Positive and Negative Syndrome Scale (PANSS) and the Global Assessment of Functioning (GAF).19,20 It was not possible to maintain masking to team allocation. This bias was mitigated by the use of the factual record of employment or education, cross-checked with other available records.

Statistical analysis

Data were analysed using SPSS for Windows PC version 17 and Stata version 11. In addition to comparisons across the two arms of the study, data were also compared in terms of those followed up v. those who left the study for the total sample and by treatment arm. Chi-squared tests with odds ratios were used to compare proportions and t-tests to compare means unless the data were highly skewed, in which case non-parametric tests were used. Random effects logistic regression models, taking account of clustering by care coordinator, were fitted including potential confounding variables: age, gender, ethnicity, best prior educational level, previous employment and clinical status (total PANSS and GAF scores).

Results

Teams were recruited and baseline motivational training completed before recruitment of patients. Training sessions were staggered to ensure maximum attendance. Attendance at baseline sessions was good, particularly by the care coordinators who were the primary target of the training and who had most contact with patients in the early intervention teams. The employment specialist, team leader and all care coordinators in the two motivational interviewing teams attended the baseline training, as did the social worker in the Midlands team. Attendance was less good for clinical psychologists and psychiatrists, with just one of three clinical psychologists and one trainee psychiatrist attending any session. Booster sessions were attended by the 2 employment specialists and by 23 of a possible total of 28 care coordinators. Young people under the care of the early intervention teams were recruited between June 2009 and April 2011. The flow of participants through the study is shown in Fig. 1.

Of the 675 young people on the case-load of the four teams, 375 (55%) did not meet criteria for inclusion in the study. Of the latter, 100 were already in employment and 150 had been or were due to be transferred or discharged from the early intervention service within 12 months. A small number could not give informed consent or were not available (e.g. in prison or abroad). Of the remaining 300 eligible patients, 160 consented but 1 withdrew before completing the baseline assessment and asked that all his data be removed. This left 159 participants who completed baseline assessments. There was no significant difference between the two arms on baseline variables. Although we did not recruit on the basis of a predetermined threshold for a desire to return to work, participants in all teams expressed a wish to work (mean score 7.8, s.d. = 2.1, from a total possible score of 10), although most also thought they would be unlikely to achieve this ambition in the near future (mean score 3.9,
Vocational rehabilitation in psychosis

s.d. = 2.0, from a possible 10). There was no statistically significant difference in the distribution of these scores between patients in the different teams or between those who completed or were lost to follow-up.

Ten participants were completely lost to both the clinical team and research staff at the 6-month follow-up point. This had increased to 24 by the 12-month point. All had discontinued contact with the clinical team and could not be traced or refused contact with the researchers. None had been in employment or education when last seen by the clinical service. There was no significant difference in demographic or clinical variables between those who were and were not lost to follow-up at 6 months or 12 months (data available from the author on request).

Table 1 shows baseline sociodemographic and clinical variables across all four teams. It is apparent that there were significant differences between the teams, with the majority of Black African and Black Caribbean patients in the London teams, the majority of Asians in one Midlands team and very few from ethnic minority populations in the second Midlands team.

**Process data**

Implementation of IPS was assessed by service-user consultants who were independent of services and the research team, using version 8 of the IPS Fidelity Scale from the Dartmouth IPS Supported Employment Center.17 Scores on this measure for the four teams ranged from ‘good’ (both London teams and the intervention team in the Midlands had scores of 111 to 114 out of a possible total of 125) to ‘exemplary’ (the control team in the Midlands with a score of 116). All four teams were rated as

GAF, Global Assessment of Functioning; IPS, Individual placement and support; MI, motivational interviewing; PANSS, Positive and Negative Syndrome Scale.
Craig et al. v. all missing were considered to be unemployed then the combined attainment (OR = 1.8, 95% CI 1.01–3.5). (OR = 4.3, 95% CI 1.5–16.6) and level of prior educational ethnicity, educational attainment, employment history and account of clustering by care coordinator and adjusted for gender, = 0.007). Finally, a random effects logistic regression taking PANSS and GAF scores confirmed significant independent effects of the direction of this analysis, patients in the combined intervention teams were more likely than those in the control teams to have attained open employment. If all missing patients were considered to be employed then the combined intervention showed 31/81 v. control 21/78 (χ² = 3.97, d.f. = 1, P = 0.046); if all missing were considered to be unemployed then the combined intervention showed 26/68 v. control 11/78 (χ² = 7.21, d.f. = 1, P = 0.007). Finally, a random effects logistic regression taking account of clustering by care coordinator and adjusted for gender, ethnicity, educational attainment, employment history and PANSS and GAF scores confirmed significant independent effects for the combined motivational interviewing plus IPS intervention (OR = 4.3, 95% CI 1.5–16.6) and level of prior educational attainment (OR = 1.8, 95% CI 1.01–3.5).

For those in employment, the hours worked per week were similar in the combined intervention group (median 30 h, inter-quartile range 19.0–37.5) and the control group (median 37.5 h, inter-quartile range (IQR) 16.0–37.5; Mann–Whitney Z = −0.231, P = 0.82). There was also no significant difference between the groups in terms of the length of time the employment lasted (intervention median 65 days, IQR 13–168, v. control median 117 days, IQR 30–168; Mann–Whitney Z = −0.993, P = 0.32). The majority of jobs were entry-level posts such as manual worker (30%) or sales assistant (42%). Other occupations included skilled trades (24%) and a few in professional occupations (4%). If only those in work at the day of interview were included, there was still an advantage for the combined intervention group (26/68 v. 10/66; χ² = 8.79, d.f. = 1, P = 0.003).

Although focused on our primary outcome of paid employment, this analysis underestimates the total occupational activity across all the teams. Thus, a number of patients worked in unpaid voluntary positions and others undertook short-term ‘cash in hand’ jobs such as helping a relative who was a self-employed gardener or writing an article for a magazine. Including these voluntary and cash-in-hand jobs effectively eliminated the difference in occupational outcomes between the teams (Table 2). The voluntary posts included working part-time in a charity shop, as a stage-hand for a rock concert, and work experience posts specially created by the local mental health services. Voluntary posts are often said to be stepping stones to employment, but this seldom proved to be the case, with only two young people moving to open employment from their voluntary activity over the course of the study. An important occupational outcome for many young people who develop a psychotic illness in their late teens and early adulthood is the return to college to complete studies and obtain formal qualifications. More of the participants in the combined intervention teams returned to formal education (28%, n = 21) compared with the control condition (14%, n = 10) over the initial 6 months of the study (OR = 2.4, 95% CI 1.1–5.6). This included returning to complete higher education courses, undertaking vocational training (leading to a recognised qualification) and, for two young people, a return to paid employment that included an educational component leading to a professional qualification (e.g. accountancy). Nearly half of the participants in the intervention teams and a quarter of those in the comparison arm by the 12-month follow-up point were engaged in either open employment or formal education (OR = 3.6, 95% CI 1.9–7.2). This included 13 individuals who engaged in both activities over the course of the year.

### Discussion

The majority of young people who experience a first episode of psychosis do so at a critical juncture in their lives, often while in their first employment. This disruption contributes to the rapid emergence of disabilities which can blight their subsequent life over many years. Although many of these young people have

IPS, individual placement and support; MI, motivational interviewing.
the same aspirations as their healthy peers, to have a well-paid job, a home and to be self-sufficient,4–6 the reality is that this ideal is achieved by relatively few, and (in the UK at least) it seems this motivation may be lost as patients become embedded in services.22–24 There are several reasons for this, but undoubtedly one of the most important is the lack of encouragement and the low expectations conveyed by many professionals. There is ample evidence from both research studies and personal accounts that testify to the negative views of clinicians who are often more concerned about the impact of work-related stress on the risk of relapse, rather than the psychological, social and financial benefits associated with a rapid return to employment.1,11,12,25 These fears of provoking relapse are largely misplaced. There is actually more evidence that prolonged inactivity is likely to lead to the exacerbation of the range of problems associated with the ‘sick role’ (loss of confidence, reduced self-esteem, decreased social contact, dependence on services and welfare benefits) than there is that returning to employment increases the likelihood of relapse.10,26,27

Early intervention teams are among the few specialist mental health teams in England that have adopted the IPS approach and have vocational workers fully embedded within their teams. This study was designed to determine whether the addition of training in strategies to address the motivational conflicts (among staff and patients) about return to work would make a difference to outcomes. The results suggest that this is indeed the case and that providing clinical staff with specific training in techniques to address patients’ (and their own) motivational conflicts may enhance patients’ chances of moving towards competitive employment. We have also demonstrated that it is feasible to involve teams working across a broad range of socioeconomic deprivation, from inner-city areas through more affluent suburban settings and a rural location. It is also worth noting that community conditions are unlikely to account for the better outcomes in the intervention teams because deprivation and unemployment were lower in the areas served by the control teams.

Study limitations
There are, however, a number of caveats. First, we cannot be certain that the better outcomes in the intervention teams were due to any particular motivational discussion between care coordinator and the young person. The motivational interviewing training was focused on the clinicians and tackled their own ambivalence as well as providing strategies to use when discussing employment with their patients. Team-wide training and discussion are advocated as part of the preparation for the implementation of IPS,28 so it could be that the observed benefit of the intervention reflects the response to the team-wide focus on an employment strategy for patients who consented to the research represented only half of those who met study eligibility criteria, and of those recruited a fifth were not traceable at 12 months, having disengaged from both the control teams and the research. Other UK-based studies of supported employment have reported similar difficulties in recruiting and maintaining participants’ involvement.18,27 Third, a lower percentage achieved competitive employment than anticipated, despite all teams employing experienced IPS workers with fidelity measure scores, suggesting more than adequate implementation of the IPS model in all sites. The low employment rate is particularly striking for the comparison teams, where only 18% of participants obtained paid work in the 12-month period. It is difficult to put these data into context as there have been only two randomised controlled trials of IPS in the UK and neither included substantial numbers of young people recovering from a first episode of psychosis. Rates of employment in the IPS arms of these studies ranged between 13% and 48%.29–31 The apparently low employment rate in our study may reflect the fact that we deliberately excluded those who were already in work at the start of the study and did not select participants on the basis of a commitment to returning to work. Finally, these results also need to be considered within the overall context of the wider economic recession that was at its height at the time of the study. They may also reflect the temporary absences of employment specialists in one intervention team and one control team, although these gaps were for similar periods.

Future research
In conclusion, this study has demonstrated improved occupational outcomes when training in how to address motivational problems was added to an evidence-based approach to employment (IPS) delivered by trained vocational specialists embedded in early intervention teams. These results encourage further, more definitive, trials.

Funding
The study was funded by a grant from the National Institute for Health Research (NIHR) under its Research for Patient Benefit programme. The views expressed are those of the authors and not necessarily those of the National Health Service, the NIHR or the Department of Health.

Suicide in the Trenches

Siegfried Sassoon

I knew a simple soldier boy
Who grinned at life in empty joy,
Slept soundly through the lonesome dark,
And whistled early with the lark.

In winter trenches, cowed and glum,
With crumps and lice and lack of rum,
He put a bullet through his brain.
No one spoke of him again.

You smug-faced crowds with kindling eye
Who cheer when soldier lads march by,
Sneak home and pray you’ll never know
The hell where youth and laughter go.
