Response to clozapine in a clinically identifiable subtype of schizophrenia

Nancy J. Butcher, Wai Lun Alan Fung, Laura Fitzpatrick, Alina Guna, Danielle M. Andrade, Anthony E. Lang, Eva W. C. Chow and Anne S. Bassett

Background
Genetic testing in psychiatry promises to improve patient care through advances in personalised medicine. However, there are few clinically relevant examples.

Aims
To determine whether patients with a well-established genetic subtype of schizophrenia show a different response profile to the antipsychotic clozapine than those with idiopathic schizophrenia.

Method
We retrospectively studied the long-term safety and efficacy of clozapine in 40 adults with schizophrenia, half with a 22q11.2 deletion (22q11.2DS group) and half matched for age and clinical severity but molecularly confirmed to have no pathogenic copy number variant (idiopathic group).

Results
Both groups showed similar clinical improvement and significant reductions in hospitalisations, achieved at a lower median dose for those in the 22q11.2DS group. Most common side-effects were similarly prevalent between the two groups, however, half of the 22q11.2DS group experienced at least one rare serious adverse event compared with none of the idiopathic group. Many were successfully retried on clozapine.

Conclusions
Individuals with 22q11.2DS-schizophrenia respond as well to clozapine treatment as those with other forms of schizophrenia, but may represent a disproportionate number of those with serious adverse events, primarily seizures. Lower doses and prophylactic (for example anticonvulsant) management strategies can help ameliorate side-effect risks. This first systematic evaluation of antipsychotic response in a genetic subtype of schizophrenia provides a proof-of-principle for personalised medicine and supports the utility of clinical genetic testing in schizophrenia.

The advent of molecular diagnostics with the potential for clinical genetic testing in psychiatry has introduced the possibility of providing personalised treatments for patients with schizophrenia.1 Through selection of effective and well-tolerated treatments, such advances promise to significantly reduce patient, family and economic burden of illness. Pharmacogenomic studies of response to antipsychotic medications have been largely hampered, however, by the complex genetic aetiology of schizophrenia.1,2 Although initial studies have suggested common genetic variants that may mediate response to antipsychotic treatments, small effect sizes and difficulties in replicating across patient groups limit clinical utility.1,3,4 As an alternative, the well-established association between schizophrenia and 22q11.2 deletion syndrome (22q11.2DS) provides an opportunity to investigate the utility of a molecular diagnosis in studying treatment response in schizophrenia. The hemizygous 22q11.2 deletions associated with 22q11.2DS are found in up to 1 of every 100 individuals with schizophrenia,5–7 representing the most highly replicated molecular subtype of schizophrenia to date.2–9 Individuals with 22q11.2DS are clinically identifiable (for example other major features include dysmorphic features, congenital heart defects and hypernasal speech) and standard testing for the 22q11.2 deletion is available at clinical laboratories.10 The schizophrenia of 22q11.2DS (22q11.2DS-schizophrenia) is essentially indistinguishable from the heterogeneous forms of schizophrenia found in the general population with respect to prodrome, age at onset, and core signs and symptoms.8,9,11–14 Although previous case reports describe some challenges,15–21 standard antipsychotic management and clinical practice guidelines for schizophrenia are currently recommended for patients with 22q11.2DS-schizophrenia.10 Clozapine is an effective atypical antipsychotic with a low risk of extrapyramidal side-effects; rare but serious side-effects, however, largely restrict its use to patients whose condition is treatment resistant.22–24 In this study, we compared the response and safety of clozapine treatment in individuals with 22q11.2DS-schizophrenia (22q11.2DS group) and idiopathic schizophrenia (idiopathic group), where there was no 22q11.2 deletion or other clinically pathogenic copy number variation. We used a long-term observational retrospective design (median >5 years) including comprehensive medical chart reviews and standard assessment methods.25

Method
Participants
The initial 22q11.2DS cohort comprised 184 Canadian adults with 22q11.2DS. Participants were ascertained through adult congenital cardiac, psychiatric and genetic services using active screening and/or clinical referrals.26,27 Of the 66 with schizophrenia, we identified 21 (31.8%) unrelated individuals who had been treated with clozapine, of these 1 patient was deceased but had ample data available for study. We excluded one individual who received two test doses of clozapine (total 18.75 mg) over a 2-day period immediately before death secondary to cardiovascular failure that was unrelated to clozapine initiation.28 This yielded a sample of 20 patients with 22q11.2DS molecularly confirmed to have a chromosome 22q11.2 deletion using standard clinical genetic testing (n=19 by fluorescence in situ hybridisation and probe from the deletion region, n=1 by clinical microarray).29,30

The idiopathic group was ascertained from a Canadian community mental health sample, primarily recruited from a
single clinic, who had direct clinical assessments for potential
genetic syndromic features using a standardised protocol and
high-resolution genome-wide research microarrays.26,31 Of 362
individuals, 42 (11.6%) were identified as ever having had a
trial of clozapine, 31 of whom were potentially eligible for the
current study (8 had no microarray results at study initiation
and 3 were deceased; these 11 excluded individuals appeared
comparable with those studied, for example, predominantly White
men, median age at onset 22 years; clozapine initiated at a median
of 31 years). A further 11 were excluded: 4 had a large (> 500 kb)
rare copy number variation (1q21.1 duplication, 8p23.1 deletion,
15q11–15q13 duplication, 16p11.2 duplication) independently
deemed ‘pathogenic’ by two clinical cytogenetic laboratory
directors using standard criteria.31,32 5 had insufficient medical
records, 1 was related to another patient and 1 had syndromic
characteristics.26,31 This yielded a sample of 20 unrelated
individuals in the idiopathic group.

Assessment of clozapine efficacy and safety
To assess clozapine-related changes in psychiatric behaviours and
functioning and adverse events, we used comprehensive lifetime
clinical summaries compiled for each patient using medical
records, extensive clinical histories and semi-structured
interviews. Patients and/or a caregiver or individual well-
acquainted with the patient were contacted by telephone or in
person for follow-up regarding the patient’s experiences with
clozapine. We recorded: demographic data, psychiatric diagnoses,
symptoms and hospital admissions, proxy measures of
functioning (such as housing, employment, relationships,
financial support), comorbid medical conditions, smoking
history, medications and doses and adverse effects. Updated (to
2013) clinical information was available for the majority (n = 35,
87.5%) of the 40 participants. One patient had died in the
22q11.2DS group and two individuals in each group were
unavailable for follow-up.

The clozapine maintenance dose was defined as the most
recent dose for patients still on clozapine. For patients who had
discontinued clozapine, the last dose before tapering for cessation
began, or before medication non-adherence was clearly
documented, was considered the maintenance dose. For patients
with more than one clozapine trial, the maintenance dose was
determined for the trial of longest duration. Adjunct antipsychotics
used during clozapine treatment at the maintenance dose were
recorded at the most recent dose. The highest clozapine dose
was recorded for the patient’s lifetime experience with clozapine.
Four patients in the 22q11.2DS group were prescribed clozapine by
study authors (A.S.B. (n = 2), W.L.A.F. (n = 1) and E.W.C.C. (n = 1)).

The Clinical Global Impression (CGI) Scale was used to
retrospectively evaluate mental illness severity and improvement
following a clozapine trial, masked to group status.25 For CGI
evaluation, the 40 comprehensive clinical summaries were
prepared using identical formatting and careful masking to
assess total improvement compared with baseline, with one being
very much improved, two much improved, three minimally
improved, four no change, and five to seven representing
minimally, much and very much worse, respectively. The CGI
scales were completed by two psychiatrists (W.L.A.F., A.S.B.) for
all 40 patients in randomised order and assessed for interrater
reliability using intraclass correlation coefficients (ICC).35 The
CGI raters had no involvement in the patient chart reviews, data
extraction and patient/caregiver follow-up contacts conducted for
the purposes of this study.

The average number of psychiatric hospitalisations per year
was calculated for each person while on and off clozapine. Both
psychiatric-related visits to the emergency room and hospital
admissions were classified as a psychiatric hospitalisation. Time
off clozapine was considered the time from first psychiatric
hospitalisation until the start of the clozapine trial, and summed
with other time periods off clozapine for patients with more than
one trial or where the medication had been discontinued
permanently. For patients where the precise start or end date of
clozapine was unclear, the midpoint date between the last
confirmed dates on or off clozapine was used.

Statistical analyses
To compare demographic and clinical variables, we used
Fisher’s exact tests for independent categorical variables and
the non-parametric Mann–Whitney U-test for independent
continuous variables to limit bias from non-normal distributions.
McNemar’s exact test and the Wilcoxon signed rank sum test
were used to assess paired categorical and continuous variables,
respectively. Odds ratios (ORs) for adverse events were calculated
using Cochran–Mantel–Haenszel statistics. A 0.5 zero-cell
correction was used, as necessary. Intraclass correlation
coefficients were calculated using a two-way mixed model35 using
the ‘INTRACC’ macro developed for SAS by Hamer.36 An ICC
equal to zero represents interrater agreement equivalent to
that expected by chance; whereas one represents perfect agreement.
The following ICC interpretation scale was used:35 poor to fair
(≤0.40), moderate (0.41–0.60), excellent (0.61–0.80) and almost
perfect (0.81–1). All statistical analyses were two-tailed and
performed with SAS version 9.2 software with statistical
significance defined as P < 0.05.

Results
Demographic and clinical characteristics are presented in Table 1. The 22q11.2DS group had significantly lower intellectual level and
fewer smokers, and non-significantly fewer White participants
and more women. All but 3 of the 40 patients were classified as
markedly or severely ill at the time of initiation of a clozapine trial
(Table 1). The median number of antipsychotics (treatment with a
different antipsychotic medication and/or the addition of an
adjunct antipsychotic) prior to clozapine initiation was high in
both groups (22q11.2DS group, 5, range 2–10; idiopathic group,
4.5, range 1–21; z = −0.62, P = 0.54).

Dosing and therapeutic response
The median maintenance clozapine dose was significantly lower in
the 22q11.2DS group (250 mg, range 50–425 mg, n = 19)
compared with the idiopathic group (400 mg, range 50–600 mg,
Butcher et al

Similar proportions (Table 2). However, even though clozapine weight gain and hypersalivation were reported in both groups in Common side-effects of clozapine, including drowsiness/sedation, Adverse effects reduction of psychiatric hospitalisations (\(\bar{z} = 0.04\)). There was no significant between-group difference in \(P\) similar in the idiopathic group (\(\bar{z} = 3.08\)) experienced at least one serious adverse event compared with none of the idiopathic group (gender-adjusted OR = 16.5, 95% CI 1.8–149.8), comprising myocarditis (\(n = 1\)), severe neutropenia (\(n = 3\)) and seizures (\(n = 8\)). One (5%) patient in the 22q11.2DS group (a 25-year-old White man) with no congenital heart defect developed myocarditis approximately 3 weeks after starting on clozapine (Table 2). Adjunct antipsychotic treatment included chlorpromazine and levomepromazine. A cardiologist diagnosed myocarditis following admission to hospital with dilated, akinetic cardiomyopathy and congestive heart failure with a 2-day history of chest tightness. The patient’s symptoms resolved rapidly with discontinuation of clozapine (250 mg). A viral cause was considered unlikely and thus the discharge diagnosis was clozapine-associated myocarditis. There were three confirmed cases of severe ‘red zone’ neutropenia (15%), defined as a white blood cell count (WBC) < 2.0 \(\times\) 10\(^9\)/L or absolute neutrophil count (ANC) < 1.5 \(\times\) 10\(^9\)/L reported in mandatory monitoring, in White female patients aged 26 (Patient 1), 37 (Patient 2), and 39 (Patient 3) years with 22q11.2DS (Table 2). None were treated with other medications clearly associated with agranulocytosis (for example carbamazepine).32,33 Documented concomitant psychotropic medications at time of neutropenia included lamotrigine and clobazam for Patient 1, valproate for Patient 2, and lorazepam (as necessary) for Patient 3. Although there are rare case reports of neutropenia and agranulocytosis in patients taking valproate,34,40 we note that Patient 2 received valproate both before and after clozapine with no neutropenia, and neutropenia resolved following discontinuation of clozapine.

The records available for Patient 1 and 3 indicated that baseline WBC prior to clozapine initiation (4.8 \(\times\) 10\(^9\)/L and

a. Fisher’s exact test.
b. Tetralogy of Fallot (n = 1), interrupted aortic arch type B (n = 1).
c. Lifetime history: 22q11.2DS group, n = 18; idiopathic group, n = 17.
d. Moderate interrater reliability (intraclass correlation coefficient (ICC) = 0.49).
e. n = 19.

\(n = 20, \bar{z} = –3.08, P = 0.002\); Fig. 1). The median dose of clozapine of the four smokers in the 22q11.2DS group was 268.75 mg. There were no significant differences between groups in the total time spent on clozapine, the length of the longest clozapine trial (median >5 years for both groups) or frequency of adjunct antipsychotic treatment at maintenance dose (Table 1). Adjunct antipsychotic treatments for six individuals in the 22q11.2DS group were: chlorpromazine (50 mg) with levomepromazine (15 mg), flupentixol (4.5 mg), haloperidol (2.5 mg), quetiapine (37.5 mg) and risperidone (n = 2, 0.5 mg and 4 mg). For five individuals in the idiopathic group, adjunct antipsychotics were: flupentixol decanoate injection (150 mg/ml every 4 weeks), perphenazine (48 mg), risperidone (2 mg) and olanzapine (n = 2 10 mg and 20 mg).

The 22q11.2DS and idiopathic groups responded well to clozapine treatment with the majority of both groups rated as much or very much improved (Fig. 2). There was similar improvement (Fisher’s exact test, \(P = 0.33\)) as rated using the CGI-I with excellent interrater reliability (intraclass correlation coefficient (ICC) = 0.65). For those maintained on clozapine for at least 12 consecutive weeks, the median number of psychiatric hospitalisations standardised per year was significantly reduced for the 22q11.2DS group (\(n = 18\); median, 0.0, range 0.0–1.90) compared with other antipsychotics (median, 0.73, range 0.15–6.35), Signed-Rank Test Statistic (5)/6 = 66.5, \(P = 0.002\). Results were similar in the idiopathic group (\(n = 17\); median, 0.09, range 0.0–4.15) on clozapine; 1.09, range 0.23–2.03 on other treatment; \(S = 44.5, P = 0.04\). There was no significant between-group difference in reduction of psychiatric hospitalisations (\(z = 0.02\), \(P = 0.99\)).

**Adverse effects**

Common side-effects of clozapine, including drowsiness/sedation, weight gain and hypersalivation were reported in both groups in similar proportions (Table 2). However, even though clozapine treatment was at a higher dose and for a longer duration in the idiopathic group overall than the 22q11.2DS group, the latter had a higher prevalence of uncommon side-effects. Half of the 22q11.2DS group (n = 10) experienced at least one serious adverse event compared with none of the idiopathic group (gender-adjusted OR = 16.5, 95% CI 1.8–149.8), comprising myocarditis (n = 1), severe neutropenia (n = 3) and seizures (n = 8).

One (5%) patient in the 22q11.2DS group (a 25-year-old White man) with no congenital heart defect developed myocarditis approximately 3 weeks after starting on clozapine (Table 2). Adjunct antipsychotic treatment included chlorpromazine and levomepromazine. A cardiologist diagnosed myocarditis following admission to hospital with dilated, akinetic cardiomyopathy and congestive heart failure with a 2-day history of chest tightness. The patient’s symptoms resolved rapidly with discontinuation of clozapine (250 mg). A viral cause was considered unlikely and thus the discharge diagnosis was clozapine-associated myocarditis.

There were three confirmed cases of severe ‘red zone’ neutropenia (15%), defined as a white blood cell count (WBC) < 2.0 \(\times\) 10\(^9\)/L or absolute neutrophil count (ANC) < 1.5 \(\times\) 10\(^9\)/L reported in mandatory monitoring, in White female patients aged 26 (Patient 1), 37 (Patient 2), and 39 (Patient 3) years with 22q11.2DS (Table 2). None were treated with other medications clearly associated with agranulocytosis (for example carbamazepine).32,33 Documented concomitant psychotropic medications at time of neutropenia included lamotrigine and clobazam for Patient 1, valproate for Patient 2, and lorazepam (as necessary) for Patient 3. Although there are rare case reports of neutropenia and agranulocytosis in patients taking valproate,34,40 we note that Patient 2 received valproate both before and after clozapine with no neutropenia, and neutropenia resolved following discontinuation of clozapine.

The records available for Patient 1 and 3 indicated that baseline WBC prior to clozapine initiation (4.8 \(\times\) 10\(^9\)/L and
5.6 × 10^9/L, respectively) were within standard laboratory norms and consistent with baseline WBC results for the overall 22q11.2DS group (mean 5.8 × 10^9/L, s.d. = 1.5 × 10^9/L, n = 17). The mean baseline WBC results for the 22q11.2DS group was lower than that reported previously for 11 309 individuals monitored by the Clozaril Patient Management System (8.3 × 10^9/L, s.d. = 2.7 × 10^9/L; t = 7.712, d.f. = 16, P < 0.0001). Notably, one of the three ‘red zone’ participants in the 22q11.2DS group (baseline WBC 5.6 × 10^9/L) exhibited persistent neutropenia on clozapine but was able to be successfully maintained on it for 8 years with an approved lowered ‘red zone’ alert zone. Such an alert, accompanied by a sore throat and fever, eventually led to clozapine discontinuation. The two other patients demonstrated further severe neutropenia episodes following a second trial of clozapine.

**Seizures and other neurological side-effects**

Eight (44.4%, n = 4 male) of 18 patients in the 22q11.2DS group experienced at least one seizure on clozapine (Table 2). Two patients in the 22q11.2DS group who had a prior diagnosis of epilepsy (one with seizures on clozapine), were not included in the analysis. No patients in the idiopathic group had a seizure on clozapine. The occurrence of seizures in the 22q11.2DS group is similar to those in the idiopathic group (P = 0.33). One of the two patients with no change corresponds to a patient in the idiopathic group with a clozapine dose < 150 mg who discontinued within 28 weeks of treatment.
was significantly higher than reported for 1743 individuals during clinical testing of clozapine (n = 61; OR = 22.1, 95% CI 8.4–57.9). In the 22q11.2DS group, non-significantly fewer (n = 3, 16.6%) had seizures when they were treated with other atypical antipsychotics compared with clozapine (S = 3.57, P = 0.059).

Three individuals had one or two seizures each on a different atypical antipsychotic (risperidone with loxapine, quetiapine with low-dose levomepromazine, and olanzapine), two of whom also had seizure(s) on clozapine.

Seizures on clozapine were typically primarily or secondarily generalised tonic–clonic seizures (electroencephalogram (EEG) findings, online Table DS1). One patient also had complex partial seizures, hypocalcaemia, and concomitant anticonvulsant medications, in two of these patients, the seizures occurred during antipsychotic management changes (changing from loxapine to risperidone, and on increase in loxapine dose).

Seizures during clozapine treatment appeared unlikely to be influenced by adjunct antipsychotic treatment; the majority of patients (n = 7, median 300, range 100–425 mg; online Table DS1). Five (62.5%) of the eight individuals in the 22q11.2DS group who had seizures on clozapine had no prior history of seizures. Three had a prior history of one to two seizures each (primarily or secondarily generalised tonic–clonic seizures, one focal motor seizure) while on other antipsychotic medications. In two of these patients, the seizures occurred during antipsychotic management changes (changing from loxapine to risperidone, and on increase in loxapine dose).

Seizures during clozapine treatment appeared unlikely to be influenced by adjunct antipsychotic treatment; the majority of patients (n = 7, median 300, range 100–425 mg; online Table DS1). Five (62.5%) of the eight individuals in the 22q11.2DS group who had seizures on clozapine had no prior history of seizures. Three had a prior history of one to two seizures each (primarily or secondarily generalised tonic–clonic seizures, one focal motor seizure) while on other antipsychotic medications. In two of these patients, the seizures occurred during antipsychotic management changes (changing from loxapine to risperidone, and on increase in loxapine dose).

Discontinuation and retrials of clozapine
At the last follow-up, the majority of patients were still being treated with clozapine (n = 13, 65% in each group). Clozapine was discontinued on initial trial in the 22q11.2DS group more commonly (n = 12, 60.0%), but non-significantly, than in the idiopathic group (n = 9, 45.0%, χ² = 0.90, P = 0.34), and for different reasons, including rare serious side-effects (Table 3). Eight of these 12 (66.7%) patients in the 22q11.2DS group had a retrieval of clozapine. Five (62.5%) retrievals were successful with clinical improvement and no further clozapine discontinuations (Table 3). The other three patients had second discontinuations because of recurrent 'red zone' neutropenia (n = 2) or Parkinson's disease (n = 1). This last patient was given a third trial of clozapine (maximum dose, 300 mg) upon relapse of psychosis but this was also discontinued, related to concerns about worsening Parkinsonism. In contrast, the reasons for discontinuation in the idiopathic group were primarily somatic complaints (Table 3). In three (33.3%) patients with idiopathic schizophrenia, there were retrievals of clozapine; after which two showed clinical improvement.

Discussion
The results of this study demonstrate the potential for clinical utility and personalised psychiatric care with a molecular diagnosis of schizophrenia. Although adults with 22q11.2DS-schizophrenia responded as well to clozapine as those with idiopathic forms of schizophrenia, including significantly reduced hospitalisations, there were clinically relevant differences. Whereas myoclonus in the 22q11.2DS group had a seizure history (online Table DS1). Less frequent clozapine treatment-emergent side-effects, including other neurological symptoms, are described in online Table DS2.

**Table 3 Reasons reported for initial discontinuation of clozapine treatment and success of clozapine retrievals in adults with 22q11.2 deletion syndrome (22q11.2DS) schizophrenia compared with idiopathic schizophrenia**

A. Denotes successful retrieval (n = 3) each: showed clinical improvement with retrieval of clozapine and had no further discontinuations.

b. One patient responded well to clozapine before the development of Parkinson’s disease and subsequent treatment changes (for example clozapine dose reduction to 100 mg with patient non-adherence and trials with adjunctive antipsychotics and electroconvulsive treatment). The other patient was treated with clozapine before discontinuing at approximately 6 months (maintenance dose 275/mg) and had a successful clozapine retrieval (maintenance dose 300mg).
individuals with 22q11.2DS are susceptible to early-onset seizures, severe ‘red zone’ neutropenia and myocarditis.

Notably, our findings of low clozapine doses and serious side-effects are consistent with previous case reports of clozapine treatment in individuals with 22q11.2DS. Reports of seven patients show a low median therapeutic dose of clozapine (200 mg, range 75–350 mg). Seizures were reported in four patients and agranulocytosis in another. The results suggest that although patients with this underrecognised subtype account for up to 1% of all patients with schizophrenia and have demonstrable efficacy of clozapine, they may be disproportionately represented in those with a rare serious adverse event on clozapine. Clinical testing for 22q11.2 deletions thus has significant implications in providing personalised management of schizophrenia.

Clinical implications

Studies of clozapine in schizophrenia consistently demonstrate its significant therapeutic benefits, including substantial clinical improvements and reductions in admissions to hospital. Findings from the current study indicate that clozapine treatment response in patients with 22q11.2DS-schizophrenia is at least as good as in other forms of schizophrenia. Importantly, despite the increased risk of serious side-effects, the majority of patients with 22q11.2DS-schizophrenia in this study currently remain well treated with clozapine. Our experience and that of others with similar clinical situations indicates that a ‘start low, go slow’ approach in the context of dose and dose titration increases the likelihood of successful outcome. In addition, careful monitoring, and prophylactic anticonvulsant medication and calcium and vitamin D supplementation may specifically help reduce associated side-effects in the context of the lowered seizure threshold of 22q11.2DS. Importantly, for patients in this study, changes such as these in management strategies largely made it possible for them to continue on clozapine, or have a retrial. Although we observed that seizures occurred in more patients with 22q11.2DS-schizophrenia during clozapine treatment than when they were treated with any other atypical antipsychotic, this result did not reach statistical significance. Studies of the neurological side-effects of other antipsychotic medications are needed for 22q11.2DS.

Standard blood monitoring protocols were sufficient to detect neutropenia, despite the increased risk observed in the 22q11.2DS group; notably, no patients progressed to agranulocytosis. The lower baseline WBC reported here and previously in patients with 22q11.2DS-schizophrenia may mediate a lowered threshold to this rare side-effect of clozapine. Larger studies with additional reports of individuals with 22q11.2DS-schizophrenia treated with clozapine are needed to clarify the potential association of the 22q11.2 deletion with increased risk of severe neutropenia and the very rare occurrence of myocarditis.

In addition to seizures, the risk of other neurological abnormalities may also be elevated in 22q11.2DS-schizophrenia. Myoclonus has been reported previously in two women patients with 22q11.2DS treated with clozapine, although in one patient myoclonic jerks were attributed to valproate. Given that individuals with 22q11.2DS are susceptible to early-onset Parkinson’s disease, the emergence or worsening of motor symptoms such as tremor and rigidity, observed in some patients in this study, could indicate a progression of neurodegenerative disease or the unmasking of a vulnerable nigrostriatal system by any antipsychotic treatment. Interestingly, there is one prior report of an individual with 22q11.2DS with early-onset Parkinsonism whose muscle rigidity dramatically worsened following a change to clozapine from fluphenazine treatment. Further studies are warranted to examine the side-effects of clozapine and other antipsychotic medications on motor functioning in adults with 22q11.2DS, especially given clozapine’s low binding affinity for dopamine receptors.

Study strengths and limitations

To our knowledge, this is the first study to demonstrate that treatment outcomes and management can show clinically relevant differences in a genetic subtype of schizophrenia. We had access to a sample of adults with 22q11.2DS-schizophrenia treated with clozapine with extensive lifetime medical records available and a matched comparison group molecularly screened to exclude pathogenic copy number variations. Replication in independent samples of well-characterised adults using comparable methods and ideally a prospective design with long-term follow-up would be desirable. However, to our knowledge, our cohort remains the largest available (in this age range) on clozapine with long-term phenotypic data. The aetiological homogeneity of 22q11.2DS-schizophrenia likely provided increased power to detect significant differences in our modest sample size.

The main limitations of the current study are the retrospective, naturalistic design and unavoidable restrictions of available data. The frequency of side-effects, especially those that are mild and less likely to be documented in clinical records, may be underestimated. The possible effects of polypharmacy, often necessary in managing adults with 22q11.2DS-schizophrenia, in mediating side-effect risks during clozapine treatment requires additional study. We note that there were no serious side-effects in the idiopathic group, which demonstrated similar rates of antipsychotic polypharmacy. Clozapine was the only medication common to the individuals with 22q11.2DS-schizophrenia who developed serious side-effects.

Further studies will also be necessary to elucidate the mechanism underlying the increased risk of rare, serious side-effects in 22q11.2DS-schizophrenia. Our sample was underpowered to detect differences with small effect-sizes between groups. We did adjust for possible gender effects on side-effect risks (for example all three patients in the 22q11.2DS group who developed severe neutropenia were women) but not for ethnicity, given that all individuals in the 22q11.2DS group who experienced serious side-effects were White (except two patients with seizures) and this would therefore not be expected to weaken the findings. However, other possible differences would include genome-wide variants modifying drug response, such as CYP enzyme genotypes, or non-genetic factors (such as smoking). The latter two factors may affect clozapine metabolism but are unlikely to have an impact on serious side-effects that are not dose-dependent (for example myocarditis and severe neutropenia) in people with 22q11.2DS-schizophrenia. They could, however, mediate seizure risk. Other factors suggested to affect generally elevated seizure risk in 22q11.2DS include rare abnormalities of cortical development (such as polymicrogyria, periventricular nodular heterotopia, cortical dysplasia). Other large copy number variations do not appear to be a major factor in 22q11.2DS.

In conclusion, the results suggest that the 22q11.2 deletion confers increased sensitivity to clozapine dosage and rare, serious side-effects. The findings provide proof-of-principle of personalised medicine in psychiatry and evidence of the utility of clinical genetic testing in schizophrenia. Molecular diagnosis coupled with targeted management strategies could reduce adverse events and discontinuation rates of clozapine. Patients...
with 22q11.2DS could represent an identifiable and more genetically homogeneous population to investigate the molecular mechanisms mediating psychotic treatment response and toxicity. Importantly, individuals with 22q11.2 deletions may account disproportionately for reports of rare, serious side-effects associated with typical clozapine. Additional reports of 22q11.2 deletions and other high penetrance genetic variants associated with schizophrenia promise to aid in our understanding of the complex etiology of schizophrenia and treatment response.

Butcher et al
A Question for Neuroscientists

Valerie Laws

Where does a memory sit, when it’s at leisure?
Where does it cool its heels, await our pleasure?
For whenever we are shown the busy brain,
We see the thoughts and memories entertain
Us, but always like honey bees in a hive,
Entering and leaving, keeping themselves alive
In restless motion, either coming in and out,
Or from lobe to lobe, bustling round about.
In through the senses’ portals in endless flow,
Or out through speech or action, what we know
Flickers from cell to cell like summer lightning,
The dendrite forests darkening and brightening
As something being stored, or being recalled,
Is passed round like a parcel: never stalled?
Never at rest? Or are there hours or days
When a memory’s not moving? When it stays
Still, drowsing like a sleepy drone,
Not being thought on, just being left alone.
So where’s its home? Its niche? Its nest?
In the nucleus at a neurone’s heart?
In many neurones? In what part
Of cell or lobe or brain does it reside
While waiting for the call to come onside?
And in what shape or form is it recorded,
Until it comes forth, smiling and applauded,
Twinkling, a galaxy of stars, each spark
Peppering our consciousness through dark
Times and good: soothing, aiding or warning,
Awake or in dreams, to make us smile at morning.
If thought, like light, can be particle, or wave,
What is memory’s photon, how is it saved?
To recall them is to move them, so which cell keeps
Each of my honeyed memories, while it sleeps?
