Evaluation of cumulative cognitive deficits from electroconvulsive therapy

George G. Kirov, Laura Owen, Hazel Ballard, Adele Leighton, Kara Hannigan, Danielle Llewellyn, Valentina Escott-Price and Maria Atkins

Background
Electroconvulsive therapy (ECT) is the most effective acute treatment for severe depression, but widely held concerns about memory problems may limit its use.

Aims
To find out whether repeated or maintenance courses of ECT cause cumulative cognitive deterioration.

Method
Analysis of the results of 10 years of cognitive performance data collection from patients who have received ECT. The 199 patients had a total of 498 assessments, undertaken after a mean of 15.3 ECT sessions (range 0–186). A linear mixed-effect regression model was used, testing whether an increasing number of ECT sessions leads to deterioration in performance.

Results
The total number of previous ECT sessions had no effect on cognitive performance. The major factors affecting performance were age, followed by the severity of depression at the time of testing and the number of days since the last ECT session.

Conclusions
Repeated courses of ECT do not lead to cumulative cognitive deficits. This message is reassuring for patients, carers and prescribers who are concerned about memory problems and confusion during ECT.

Declarations of interest
None.

We excluded patients with schizophrenia, because of their known cognitive deficits. Patients who were not fluent in English were not included in this analysis.

The mean age of patients at the time of their last assessment was 56.3 years (s.d. = 15.8, range 21–88) and 71.9% of them were female (n = 143). The majority had unipolar depression (n = 166, 83.4%), the remaining 33 had bipolar affective disorder, but everybody included in this analysis was treated for depressive episodes. The average number of ECT sessions that patients had prior to their tests was 15.3 (s.d. = 23.2, range 0–186). Figure 1 shows the distribution of the numbers of ECT sessions that patients had prior to their tests.

**Statistical analysis**

Our aim was to evaluate whether the cumulative number of ECT sessions received during the lifetime of patients prior to testing was inversely correlated with their performance on the cognitive tests. We obtained histories of previous courses and recorded the total number of ECT sessions they had received prior to each test. As other factors can influence cognitive performance, we included the following four covariates: age, number of days since last ECT session, severity of depression and the number of times the patient had undertaken the test previously. Age is an obvious confounder, as cognitive performance declines with age. It has been shown that cognitive performance is worse in the first 3 days after an ECT session and tends to improve with time. We recorded the number of days since the last ECT session (for those who had no previous ECT sessions, we entered an arbitrary, but very large number of 10,000 days (about 30 years), in order to keep these assessments in the analysis). As these data were extremely skewed, we log-transformed the number of days since the last ECT. As our cognitive testing always includes an objective measure of the severity of depression (the 24-item Hamilton Rating Scale for Depression, HRSD-24), we included these scores as a covariate, expecting that patients who were more severely depressed might perform worse. The number of times a test had been undertaken previously by a patient was also included as a covariate in order to control for the possibility that patients improve their performance with practice. As some patients had undertaken tests on more occasions than others (between one and seven occasions), we also wanted to control for the potentially disproportionate effect of inter-individual differences. We therefore used a linear mixed-effect regression model with random effects attributed to individual patients and fixed effects to the four covariates listed above. We used the R statistical package with the library lme4 (function lmer). As a secondary analysis we compared the first and last cognitive tests of those patients who had 13 or more ECT sessions between these tests (more than a standard ECT course of 12 sessions). We used a paired samples t-test to compare these pre- and post-ECT results.

**Results**

Results are presented in Table 1. We show the effect size and statistical significance of the effect from the number of ECT sessions and the four covariates on cognitive performance. Effect size denotes the change on the cognitive score with each unit of the covariate (such as each year of age or each ECT session). Deterioration is always indicated with a negative sign of the effect size, whether it refers to reduction in score (for example verbal fluency), or increase in the time needed to perform a test (Trail Making and Reaction Time), or increase in the Cognitive Failures Questionnaire (CFQ) score. The number of ECT sessions prior to testing had no significant effect on any of the tests. The other covariates had statistically significant effects on the results, in the predicted directions.

The variable with the strongest effect on the tests was age, with performance significantly declining with increasing age on all tests except the CFQ. The CFQ is a self-assessment of cognitive/memory problems and the results suggested that older patients complained less of cognitive problems. The next factor influencing the results was the severity of depression at the time of testing, which adversely (and significantly) affected seven of the nine tests.

![Fig. 1](image_url)  
**Fig. 1** Number of electroconvulsive therapy (ECT) sessions received by patients prior to the assessments.  
The highest number of tests done were prior to their first-ever electroconvulsive therapy session (n = 122).
Patients showed significant improvements in performance with increasing time-gaps since the last ECT session on two of the tests (memory and Trail Making A). Practice (repetition of the tests) significantly improved the performance on two tests (Reaction Time and Trail Making A).

As a secondary analysis we compared the pre- and post-ECT results on 55 patients who had 13 or more ECT sessions between their first and last cognitive assessment (i.e. more than the standard duration of a single ECT course of up to 12 sessions). The median number of ECT sessions these patients had between the tests was 20 (range 13–156). We used paired samples t-tests and present the results in Table 1. All results improved, two of them improved significantly. The improvements are most likely because of improvements in depression at the end of a course or at follow-up (HRSD-24 scores were on average 29.1 at the first and 14.7 at the time of the last tests).

### Discussion

**Findings from other studies**

Memory problems and fears of cognitive decline are probably the biggest deterrents for patients’ willingness to undergo ECT.7 The internet abounds with reports of people complaining that ECT has destroyed their memory and mainstream media tends to portray it as a barbaric treatment.7 Complaints of memory loss regarding ECT are very frequent and were also reported by many of our patients (the tests in the Appendix do not measure retrograde amnesia). However, a meta-analysis9 showed that the biggest deterrents for patients’ willingness to undergo ECT are memory problems and fears of cognitive decline. Memory problems and fears of cognitive decline are probably the biggest deterrents for patients’ willingness to undergo ECT.

**Main findings**

To our knowledge, the current study is the first of its kind, reporting on 10 years of cognitive data collection on consecutive ECT patients, where each patient’s lifetime number of ECT sessions has been recorded and included in the analysis. The results actually improved after 6 months of maintenance ECT. It has been suggested that the risk of cognitive impairment during longer courses of maintenance ECT may even decrease, because of the longer time intervals between sessions.22

n: number of patients; MMSE: Mini-Mental State Examination; CFQ: Cognitive Failures Questionnaire; HRSD: Hamilton Rating Scale for Depression.* Results with P>0.05 are shown as non-significant (ns). No correction for multiple testing is applied. Effect size indicates the degree of change on the cognitive test score by each unit of the variable. For example for the variable age, each year reduces the MMSE by 0.07 points, i.e. a patient who is 50 years older than another one, scores on average 3.5 points lower. All effect sizes have been converted so that a minus (−) sign always denotes a deterioration.

1. As a barbaric treatment. 7
2. Complaints of memory loss regarding ECT have been reported by many of our patients (the tests in the Appendix do not measure retrograde amnesia).
3. However, a meta-analysis9 showed that the biggest deterrents for patients’ willingness to undergo ECT are memory problems and fears of cognitive decline. Memory problems and fears of cognitive decline are probably the biggest deterrents for patients’ willingness to undergo ECT.
4. The internet abounds with reports of people complaining that ECT has destroyed their memory.
5. Main findings**
6. To our knowledge, the current study is the first of its kind, reporting on 10 years of cognitive data collection on consecutive ECT patients, where each patient’s lifetime number of ECT sessions has been recorded and included in the analysis. Our results show a lack of cumulative cognitive deterioration with an increasing number of ECT sessions. In contrast, other covariates, such as age and severity of depression, produced clear trends in the expected directions, suggesting that we have not missed trends.
where they exist, because of noise in the data or bias that can occur in an open study. An example of this is presented in Fig.
2 that shows a clear deterioration of the scores on the Complex Figure test\(^2\) with increasing age of the patients, but there is no such trend with increasing number of ECT sessions. The results are supported by our observations on patients who accumulated the highest numbers of ECT sessions over the 10-year period of monitoring and showed no deterioration in their performance (Table 2).

</tbody>
</table>

\(^a\) Paired samples \(t\)-tests. All results indicate improvements (the minus signs for the last four tests also suggest improvements, as the tests were completed faster, or in the case of the CFQ, the patients rated themselves less impaired).

**Limitations**
As an open, uncontrolled study, our work has limitations that we acknowledge. For example, some patients might have had early stages of dementia or underlying cerebrovascular disease, which could lead to a reduced cognitive reserve. To reduce this potential problem, we re-analysed the results while excluding people over the age of 65. The lack of effect from the number of ECT sessions remained for all cognitive tests (data not presented). The effect size caused by age was reduced, as expected, but remained in the same direction. It is also possible that the patients who persist with more ECT sessions may be those who had fewer cognitive side-effects, so that those who have more ECT sessions will tend to have fewer adverse effects. This potential bias is difficult to address in a naturalistic study, and we can only report that many of our patients on maintenance ECT or repeated courses complained of subjective memory problems and stopped their treatments on many occasions, i.e. they did not appear to be more tolerant of side-effects. We were unable to measure any cumulative retrograde amnesia because of the longitudinal nature of the testing (patients are more likely to forget the original events, if tested 1 or more years later, when they come for new ECT courses).

**Implications**
We find that discussing the cognitive results with patients is highly reassuring for them, as they can see for themselves that their cognitive performance remains stable. This has helped their decisions when accepting further ECT courses or maintenance treatment, something that might have been unacceptable to them or to their treatment teams only a few years ago. Our results suggest that patients can have repeated courses or maintenance ECT without this resulting in long-term cumulative cognitive deterioration. We hope that this study will help to counter the negative public view of ECT, which may be having an effect on prescribers and thus aid in the appropriate prescribing of this effective treatment.

**Fig. 2** Scores on the Complex Figure immediate recall test.
The score on the Complex Figure immediate recall test reduces with the increasing age of patients (a) but not with the increasing number of previous electroconvulsive therapy (ECT) sessions (b). The maximum score for a perfectly memorised and reproduced figure is 36 points.\(^2\)
